### I INTRODUCTION: THE STUDY OF HUMAN FOOD INTAKE

#### A Context

We live in a society that is virtually obsessed with the influence of food on health, energy intake, and body weight regulation. While much of life in preindustrial societies has been concerned with locating, obtaining, or cultivating adequate quantities of appropriate foods, many people living in industrialized societies spend considerable time and effort in attempting to avoid excess food intake. For many individuals this has become an active process. The food industry in any Western society is worth billions of dollars per annum. In addition, consumers spend several billion dollars on products they hope will help them avoid excess food intake or remedy the consequences of overconsumption. Feeding and food are central to our health and well-being. Food characterizes cultural grouping and identifies social and religious occasions. The composition of the diet we eat is now considered a primary cause of morbidity and mortality [e.g., obesity, coronary heart disease (1)]. Our growing knowledge of the effect of the diet on health offers a potential means of preventing certain illnesses or alleviating the effects of others through nutritional support. The market economy has recognized the potential in this area and now “func-

tional foods” and “nutraceuticals” are available with the promise of increased consumer longevity, health, and well-being.

A key problem, particularly for the layperson, is that it appears difficult to pinpoint the major facts that scientists have discovered about food intake. What are the salient discoveries in the area of appetite and energy balance? Researchers often find this a very difficult question to deal with. Why is this so? Is it because there are no facts (universally agreed statements)? Or is it because we are dealing with a form of *behavior* that operates according to probabilistic rather than deterministic principles? This also has implications for those seeking to unravel the specific molecular mechanisms thought to be important in controlling feeding behavior. There is a further reason why facts about food intake appear to be relatively rare. Reliable quantitative and qualitative facts about food intake appear difficult to obtain since the act of measurement may influence what is being measured. This is exemplified by current concerns over the nature and extent of misreporting of dietary intakes (2). Even more frustrating to both the scientist and the general public is the problem of communicating the results of research to a population eager to understand how to regulate their own body weight and improve health and fitness. As soon as the media reduces research results to readily digested “sound bytes” deemed fit for public consumption, the informa-

tion being relayed to the public has become distorted. This is often so in science. However, the field of ingestive behavior, energy balance, and obesity is constantly the subject of media interest, so this problem of media misrepresentation of our results is more acute.

It should be kept in mind that food intake is a form of *behavior* commonly believed to be under voluntary control. This behavior can be described by terms such as amount of energy ingested, structure of dietary pattern, or macronutrient profile. But all of these terms are the consequences of behavior (food being seized by the hands and transported to the mouth). Therefore a study of food intake should concentrate on the way in which environmental, cognitive, or biological events can be translated into effects upon the act of behavior. It is also worth mentioning that “not-eating” (one aspect of which is postingestive [PI]-satiety) is also a form of behavior. Consequently, events that prevent eating are also important. Understanding how energy balance is maintained requires an understanding of the forms of behavior that promote weight stability. Understanding the etiology of obesity and developing strategies for its treatment requires an elucidation of the mechanisms that influence the behaviors leading to weight gain and those that can bring about sustained weight loss, respectively.

It is also important to recognize that certain environmental contexts favor or constrain specific forms of behavior. For example, a calorimeter environment constrains the ability of a subject to move about and select food. In a given environmental context, eating behavior bridges the gap between the nutritional environment and the physiological/biochemical mechanisms of weight control. One view of appetite regulation is that it may be seen as the adoption of forms of behavior that ensure an appropriate supply of energy and nutrients for the optimal performance of the organism in a given environment. It follows that strategies of appetite regulation appropriate to a hunter-gatherer are not necessarily the same behavioral strategies as those of a bank clerk.

## **B Eating Behavior or Fuel Intake?**

Food consumption is the target of scientific research for a number of different researchers including physiologists, nutritionists, psychologists, biochemists, endocrinologists, and, increasingly, molecular biologists and geneticists. All of these researchers share, as one of their primary goals, the attempt to understand the mechanisms responsible for human food consumption. However, the terminology that refers to this endpoint may

appear discordant. For one group of researchers the phenomenon usually measured is called eating, human feeding, or food intake. In other scientific domains the phenomenon is called dietary intake, energy intake, or, more commonly, spontaneous energy intake. Differences are also apparent at the level of scientific practice. The first group is often concerned with qualitative aspects of eating such as food choice, preferences, and the sensory aspects of food together with subjective phenomena such as hunger, fullness, and hedonic sensations that accompany eating and which are sometimes regarded as causal agents. The second group is primarily concerned with quantitative aspects of consumption and with the energetic value of food; at the present time, particular importance is attached to the macronutrient composition of food and its impact on energy balance (3,4).

The identification of food consumption as either a form of behavior or as fuel intake is not just a semantic issue. It is fundamental to the theoretical paradigms we develop to explain the existence, nature, and strength of mechanisms concerned with the control of food intake. The study of human appetite should attempt to reconcile these different approaches to the subject. What is the relationship between the pattern of intake of meals and snacks (behavioral profile), the tastes and other sensory attributes of the foods consumed (qualitative pattern), and the total food consumed over a 24-hr period (spontaneous energy intake) together with the proportions of macronutrients (fuel balance)? How do the physiological consequences of nutrient ingestion influence subsequent feeding behavior? Is obesity brought about by enhanced feelings of hunger, weakened PI satiety, sensorily induced overconsumption, or hedonically mediated maladaptive food choices? Or is obesity a result of errors in processes governing energy balance such as inappropriate oxidation of fuels or different neuroendocrine responses to varying dietary intakes? Most critically, is energy balance truly regulated in humans and if so, under what conditions and to what extent?

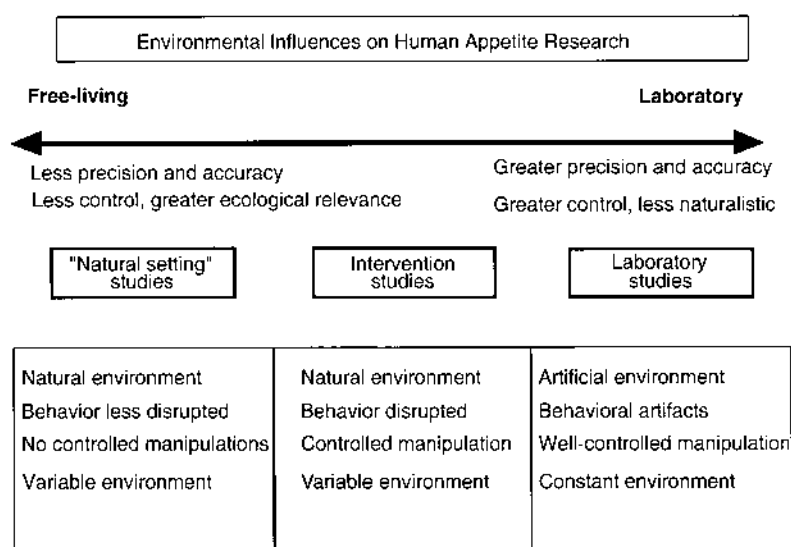

If appetite research is to explain the mechanisms responsible for human food consumption, it must be multidisciplinary in nature. The outcomes of studies on feeding behavior are probabilistic rather than absolute. They are not as empirically reproducible as, for example, the behavior of molecules in solutions, or of hypothalamic peptide levels in response to changes in energy balance. This means that the experimental environment can be particularly important in determining the outcome. A specific issue or factor thought to be important in influencing feeding behavior needs to be examined in

such as eating styles, rate, and duration as potential determinants of intake, to more quantitative work based on the effects of controlled nutrient interventions on energy and nutrient intakes. A number of excellent reviews have discussed experimental techniques and methods associated with the study of feeding behavior (5-7). Various methods have their own inherent strengths and weaknesses. It is probably worth keeping in mind that neither calorimeter/cubicle environments nor free-living systems have a monopoly on scientific truth. The eating that goes on (and the nutrient and energy computations that are subsequently made) will be closely related to the nature of the research environment. For example, Shepherd (8) notes that sensory attributes of foods associated with salt, sugar, and fat may be important in influencing food choice when specific sensory measures of foods are related to nutrient intake or food consumption in the laboratory. In the real world the picture is much less clear. There is as yet little convincing evidence that the same sensory attributes determine salt, sugar and fat intake in free-living people. Other factors such as convenience, price, nutritional beliefs, availability, brand image, and cultural and social influences are likely to be more important. Thus the "noise" created by environmental influences in the real world obscures the relationships observed in the laboratory. This "noise" is important, however, since it influences food choice in the natural environment of the subjects.

## II METHODOLOGICAL APPROACHES TO STUDIES OF HUMAN FOOD INTAKE

## A Precision Versus Naturalness

There has been a general shift in emphasis in recent years from qualitative studies examining factors

**Figure 1** Constraints and limitations that the experimental environment places on studies of human feeding. In general, the environment ranges from totally free-living, which is realistic but very difficult to make measurements in, to the laboratory, where measurement are easy but may be contaminated by artifacts due to the artificiality of the laboratory surroundings.

Studies are therefore measuring not “how the biobehavioral system functions,” but how it functions under different circumstances. Is any of this relevant to how the system functions when it is not in an experiment and not being measured? Currently we favor (where possible) a methodological approach which attempts to bridge the gap between the laboratory and the real world by overlapping protocols that explore the same issue in different environmental contexts. Few individual studies are likely to unequivocally resolve major issues in appetite research.

### **B Demand Characteristics**

Although as scientists we may suppose that we can investigate the food intake of human subjects as if it were a piece of tissue in a test tube, this is unlikely to be the case. In any experimental circumstances subjects bring with them their past history of eating, beliefs, about food, and also their beliefs about what they are supposed to do to be a “good subject”. These beliefs, which will influence the volitional control over responses (namely eating), are often referred to as “demand characteristics” and are widely ignored (by researchers).

Misreporting of dietary intakes is a case in point (2). It may be that the more we bombard the public with information about what we think they should eat (e.g., a low-fat diet), the more they tell us they are eating what they think we want them to eat.

### **C Power, Sensitivity, and Effect Size**

These issues are of course relevant to all research but may assume special importance where a form of behavior is the measured variable. This is because there is likely to be large intersubject variability. As an example, attention can be drawn to short-term studies on appetite using some variant of the preload test meal paradigm. The problem concerns negative outcomes, i.e., where manipulations produce no significant effect (on the test meal intake). Negative outcomes may obviously arise from experiments conducted under low power (the type II error). This could be brought about by small numbers of subjects, small manipulations (at the border of detection threshold) and noise in the system. In certain cases an effect size of 10% may not be statistically significant. This can be contrasted with an epidemiological type of study using hundreds of subjects in which an effect size of 0.05% may be statistically significant. In these cases different arguments apply to achieve the optimum interpretation.

For those small-scale studies that fail to detect a change in the dependent variable, a problem of interpretation arises. Is the manipulated (independent) variable truly without effect, or is the experimental system insensitive? Most scientists could design a legitimate-looking experiment, whose methodology could pass peer review scrutiny, but which would inevitably lead to a negative outcome. It has been pointed out that the major problem to be overcome in biobehavioral experiments is the type II error (not the type I, which most scientists dread because they can be accused of fudging the data). The preload paradigm is vulnerable to type II errors from a number of sources such as small quantity of nutrient given or small number of subjects, or the test meal may be consumed at a time when the effects of the preload have decayed to the point where they are no longer significant. Studies conducted in the clinical setting are vulnerable to both type I and type II errors, often because of small sample sizes. Type I errors can occur due to confounding factors such as secondary complications of disease or medication.

### **D Relevance of Questions Asked and Veridicality of Results**

Research strategies should be formulated to address key theoretical or practical issues that are important to the study of human feeding behavior. The research question asked will, in part, influence the interpretation of results. For example high-fat, energy-dense diets promote higher energy intakes than lower-fat, less energy dense diets (9–11). The common interpretation of this result is that fat is poorly recognized by the body and that dietary fat per se promotes excess energy intakes. Other studies show isoenergetically dense high- and low-fat diets to produce similar energy intakes (12,13). These observations have led to a somewhat confused debate on the role of energy density in determining energy intake. In reality dietary fat, energy density, and their effects on energy intake are interrelated (14).

There is relatively little standardization of definitions and approaches in this area of research, and this often makes comparisons of studies difficult. Furthermore, the problems of precision versus naturalness demand characteristics and of sensitivity mean that the literature is awash with studies that provide conflicting results about the same issue. It is often only possible to gain a clearer view of an issue by examining all of the studies that have addressed that issue after careful consideration has been given to

methodologies employed. The literature on the influence of sweetness on appetite, and publications on the influence of dietary fat on PI satiety and the role of CCK as a PI satiety hormone are three clear examples where a number of conflicting results can be obtained from various studies in the literature. At the present time there is a considerable degree of selective presentation of research results by interested parties who aim to use the scientific literature to market products which may or may not influence human feeding behavior or energy balance. The appetite literature is a spin doctor's paradise. It is therefore important to consider all of the literature on a given area. Researchers have a responsibility to acknowledge the limitations of their own experimental designs and to avoid overgeneralizing results or drawing premature conclusions from individual studies conducted in specific experimental environments, on small numbers of subjects. Since the majority of positive results usually provide indirect support for a hypothesis, the limitations of that support should be acknowledged. The perfect experimental protocol to study human feeding behavior does not exist.

#### **E Bottom-Up or Top-Down Research?**

There is currently a tendency to view the relative "sexiness" of biological science in terms of its ability to explain biological systems at the molecular and biochemical level. However, for any mechanism to be important to feeding behavior and body weight regulation it must operate physiological conditions in the intact animal. We believe that it is useful to study human feeding by considering the way that feeding behavior operates as a system within the intact person. In addition, an understanding of how the intact system operates can be used as a reference when attempting to interpret the mechanisms underlying the development of obesity. After all, overweight and obesity now affect the majority of Western adults going about their normal lives. It is equally important to examine how changes in the key features of the system may affect its overall functioning, for example, by understanding the role of CCK in meal termination and the maintenance of PI satiety. However these components should always be viewed as parts of a more complex system, rather than the prime movers in a simple feedback loop. It is therefore necessary to attempt to understand the nature of the system and how it responds to changes in the nature in the environment.

#### **F The Thorny Question of Regulation**

It is often assumed that the "natural" state of the subject in the laboratory, when not subject to an experimentally induced manipulation, should be one of energy and nutrient balance regulation. There is no clear reason why this should be the case, especially in short-term experiments. Indeed, given that > 50% of the adult population are now collectively overweight and obese (15), perhaps the assumed "nonmanipulated" state should be characterized by a tendency to overeat! Nevertheless, experiments that claim to address the issue of energy balance (EB) regulation should include a no-treatment control, in which subjects should be in approximate EB. If subjects are in a gross energy imbalance on such a "control," then the effect of the experiment itself on the "regulatory" system under investigation should be given serious consideration.

### **III THE NATURE OF THE APPETITE SYSTEM**

#### **A Behavior of the Appetite System**

Feeding is determined by a redundant biological system which operates through changes in behavior (by redundant we mean the system is actually a series of overlapping subsystems, which do not all need to be fully operational or intact for the whole system to function appropriately). The physiology of appetite is therefore the physiology of feeding behavior. Anatomically, this system can be divided into the central nervous system and the neural pathways, which communicate with peripheral physiology and metabolism (Fig. 2). The whole system operates through changes in behavior in response to changes in the internal or external environment. Both central and peripheral factors operate together to evaluate and reinforce "appropriate" responses and to avoid inappropriate forms of behavior. The adaptability of this system lies in its redundancy. The fact that changes in plasma profiles of metabolites or stores of nutrients do not translate directly into feeding behavior is an important feature of a flexible system capable of adjusting to changes in the environment by learning about the sensory and physiological consequences of feeding-related actions. These aspects of feeding behavior are all too often not appreciated or even ignored by those exploring molecular mechanisms of energy balance control. In spite of the fact that there are few clear facts about food intake,

**Figure 2** Anatomy of the human appetite system is represented by the relationship between peripheral physiology and the central nervous system. Only the main sites of physiological signals thought to be important in producing feedback signals that affect feeding are outlined. It is of note that all putative signals identified operate along the sequence of ingestion, absorption, metabolism, and storage. All such putative satiety signals have other primary functions.

there do appear to be a number of well-understood ways in which the system usually behaves, or its probabilistic outcomes.

1. Feeding behavior is governed by a redundant system that has numerous afferent inputs. Not all of these inputs are necessary for the system to function. Feeding behavior can change in a number of measurable ways such as meal size, frequency, and the composition of foods selected, or the rate and manner in which foods are ingested.

2. The system uses multiple sensory cues to learn about the consequences of ingesting certain foods. Mimicking the cues associated with certain foods can therefore, transiently at least, “mislead” the system.

3. The system is sensitive to certain changes in the external and internal environment (e.g., temperature or pregnancy, respectively) and to changes in the supply of energy and nutrients. With respect to energy and nutrients, the sensitivity of the system (i.e., the capacity of the system to recognize changes in the environment) can often be greater than its responsiveness (i.e., tendency to alter behavior in order to maintain the constancy of the internal environment). This may in part due to the plasticity of intermediary metabolism in response to changes in energy and nutrient intake.

4. Evolution has selected our physiology and behavior to favor overconsumption rather than underconsumption (16). This means that the system is more responsive to deficits in energy and nutrients than to increments. Being overweight is probably the result of largely “normal” feeding responses when exposed to a Western diet under modern sedentary conditions.

5. The system tends to exist in equilibrium between energy intake and expenditure that maintains a stable body weight. This equilibrium can be disrupted in such a way that shifts body weight upward. A new equilibrium may then be achieved at a higher body weight.

6. The system is interconnected with other biological systems that influence motivation and behavior. Other external and internal influences can greatly perturb the system in such a way that food (energy and nutrient) intake patterns become maladaptive. Other biobehavioral drives can override and distort the cues associated with feeding. This is especially so in the genesis of eating disorders.

At the present time there is considerable doubt in our minds about the presence of regulatory signals that protect humans from slow, continuous weight gain. This is especially so given that over half of the adult population of the Western world are overweight and obese (15). Why does energy intake rise above energy

expenditure? Why is it that a decrease in energy expenditure does not exert a restraining effect over food intake? (Are these the same questions?) Why does a positive energy balance fail to generate a negative signal to suppress food intake? Does the body contain a mechanism(s) capable of detecting a positive energy balance (or positive nutrient balances)?

Can we attribute current secular trends in body weight to a greater per capita drive to consume more food and energy, or could it be that the mechanisms concerned with resisting overconsumption are simply too weak?

## B Satiety Signals

Some physiological responses which follow food consumption are believed to terminate eating and/or maintain inhibition over further intake. These responses are usually referred to as “satiety signals” (17). What are the features of foods that are believed to be monitored and which give rise to “satiety” signals? What is the status of the putative “satiety” signals?

It has been assumed or claimed that volume, weight, energy content, macronutrient proportion, and energy density may all be monitored and constitute the source of specific satiation or postingestive (PI) satiety signals. These may be divided into general factors (e.g., weight, volume) which apply to all foods, and specific factors (nutrient content, taste, and smell) which depend on the particular food consumed. Why should weight and volume appear as important features that affect food intake in some studies? (A liter of water would have weight and volume but would provide no energy or nutrients.) The ultimate function of satiation and PI satiety signals is to monitor the biological value of foods and to play a role in the processing of ingested nutrients (all physiological signals involved in satiation, e.g., rate of gastric stretch, release of CCK, gastric emptying, nutrient oxidation, etc., have functions in addition to their role in a negative feedback system). A satiety signal is a function assumed by some underlying physiological property. Given a history of food seeking and consumption, it is inevitable that weight and volume of food will have become associated with (conditioned to) the important biological components of food, namely, energy value and nutrient composition. The system has learned how to operate in a real environment, and the objective of the system is to produce a veridical response.

Brunswik's theory of perception provides a model for understanding this (18). Weight and volume are learned cues with high functional validity (proximal

cues that correlate well with more distal cues such as hormone release contact with gastrointestinal receptors, etc.). This is why weight and volume often appear to be important monitored variables (rather than energy or nutrient content) when nutritional composition of food has been surreptitiously manipulated. The system is operating sensibly according to its previous experience, but it does not mean that weight is fundamentally more important than energy content. Indeed, we have recently shown that the macronutrients protein, carbohydrate, fat, and alcohol, together with water and energy density, collectively account for ~40% of the total variability in energy intake in 102 adults, self-recording their food intake for 7 days. However, each individual dietary component only explained a relatively minor proportion of variability in energy intake, suggesting that no one single dietary constituent has an overriding effect on energy intake (14).

## C Satiation and Satiety

In discussing the function of “satiety signals” it would be useful to specify what aspects of eating behavior they are supposed to inhibit. Is their function to prevent weight gain? Some authors have distinguished between intrameal and intermeal satiety (19); others, such as Blundell (17), have called these process satiation and PI satiety. They distinguish between events which (i) bring eating to a halt and (ii) maintain inhibition over further eating after consumption—so-called postingestive satiety. For the purposes of this work, “satiation” refers to intrameal satiety or the process that brings a meal to an end; “postingestive satiety” (abbreviated to PI satiety) refers to the inhibition of eating between meals (intermeal satiety).

In considering the control of patterns of food intake it would seem important to distinguish between those factors (in food, in the biological system, or in the mind) that operate to adjust either the size of an eating episode as the interval between episodes. For example, CCK is often referred to as a satiety hormone; is this correct? The original studies carried out by Smith and colleagues indicated that CCK terminated eating in sham-feeding rats (20). Subsequent studies indicated that CCK reduced meal size but did not influence the frequency of meals (21). Therefore CCK should more correctly be termed a satiation hormone.

This analysis draws attention to those factors that influence food (1) while it is being eaten and (2) after it has been consumed. It would be expected that weight and volume would influence satiation, but not PI

**Figure 3** Schematic representation (not to scale) of the relationship between the subjectively expressed constructs of motivation in relation to feeding, and their relationship to quantitative and qualitative feeding behavior.

satiety. Evidence suggests that this is so (14). Additionally, the palatability (and variety) of food would exert a major influence during consumption but less influence afterward. It may be inferred that cognitions would be markedly different during and after ingestion. Consequently, biological, environmental, and cognitive influences differ during the operation of satiation (intrameal satiety) and (intermeal) satiety. As regards overconsumption, there is little if any direct evidence that satiety signals function in a manner consistent with mechanisms geared to the tight regulation of body weight. It follows that speaking about satiety “in general” can be quite confusing. Conceptual understanding would be improved by an increase in semantic precision. A scheme illustrating the relationship among hunger, appetite, satiation, and PI satiety and their purported influence on feeding behavior is illustrated in Figure 3.

#### D The “Hunger State”

In 1955 Mayer pointed out that one of the key features of a short-term model of food intake is that it should be able to account for the hunger state (22). As mentioned above, this does not just have theoretical significance. There is an immense interest in pharmacological agents as tools that can be used to manipulate the hunger state (23). Parenthetically, it is of academic, and perhaps applied, interest to consider whether hunger and satiety can be dissociated. Being able to blunt the drive to eat

should enhance compliance on weight-reducing programs. Being able to increase the drive to eat may increase longevity and quality of life in patients experiencing cachexia. Understanding how to manage hunger and satiety also has important implications for the nutritional support of a number of clinical conditions. One of the great benefits of using human subjects is that they can be asked about their sensations and motivations. Understanding the profile of physiological changes that attend and underlie changes in the hunger state offers key sites for intervention and manipulation of the hunger state. Both indices of carbohydrate oxidation (24) and a preprandial drop in plasma glucose have been shown to predict the onset of feeding in rats (25) and humans (26). Furthermore, in animals, abolition of the small but reproducible preprandial drop in blood glucose, by a small intravenous infusion, has been shown to inhibit eating for several hours (27). Under these conditions satiety is maintained and hunger is inhibited.

While there is little evidence that satiety signals strongly defend against overconsumption, there is ample evidence that acute (28,29) or prolonged negative energy balance (30) leads to an elevation of hunger. In extremis, significant loss of body tissue leads to an obsessive and unabating drive to eat. Understanding how the intact system operates and which physiological events underlie changes in motivation to eat and feeding behavior can help unravel and manipulate the mechanisms that influence meal

size, frequency, and composition. New technological advances now enable real-time monitoring of brain activity and neurendocrine profiles (31). Bringing these approaches together with methods used to monitor human feeding behavior will provide unique insights into the physiological processes underlying normal daily fluctuations in energy and nutrient balance. By doing this it may become possible to explore how these mechanisms are perturbed in disease states. Conversely, specific disease states can shed light on the normal functioning of intact processes involved in feeding behavior. Determining the mechanisms that influence feeding behavior necessarily entails understanding how parts of the system interact (i) with the

environment (especially the food component) and (ii) with each other to facilitate or inhibit eating and selection of foods.

#### IV COMPARTMENTS OF THE APPETITE CONTROL SYSTEM

Figure 1 illustrates the anatomy of the system, its components, and their main functions. Figure 4 illustrates the way in which physiology and behavior interact in their response to food and food-related environmental stimuli. Together, these two figures outline the nature of the system. The biobehavioral

**Figure 4** Interaction between physiology and behavior in their response to food and food-related environmental stimuli. It is notable that food elicits potent cognitive, learned behavioral and physiological responses which together determine the feeding strategies of an individual.

system controlling feeding can be artificially divided into the following components:

1. Orosensory components
2. Gastrointestinal components
3. Circulating factors such as hormones, peptides, cytokines, and nutrients
4. Nutrient stores—gut contents, glycogen, muscle, and adipose tissue
5. Nutrient metabolism—whole-body ATP turnover, cellular mechanisms associated with oxidation of the major metabolic fuels, e.g., sodium pump activity
6. The central and peripheral nervous systems including neurotransmitters, peptides, and other centrally acting compounds

These components of the system interact to produce facilitatory or inhibitory contributions to overall feeding patterns. Most components of the diet that are ingested are likely to act at multiple sites. Simply drinking a glass of water will influence gut motility, osmoreceptors, hormones (e.g., ADH), and the central nervous system.

#### **A Orosensory Components**

Nutrient-associated orosensory components of food are generally believed to provide facilitatory signals which increase food intake. However, it is of interest that removal of the sense of smell barely inhibits the intake of readily available food in pigs, presumably because the animals will learn to use other cues (32). Clearly, for many animals, olfaction is critical to the location and acquisition of foods. When combined with learning, olfaction is a primary cue for identifying foods as being acceptable or not. As Le Magnen (33) puts it, "The particular property of the olfactory system, compared to taste, is to individualise practically all active molecules by a discriminable odour. . . ." Taste, texture, and smell of foods warn against toxins and other damaging components of food. The strength of this mechanism is indicated by the phenomenon of conditioned aversion to foods that have produced subsequent illness (34–36). Rozin suggests that rats learn sensory preferences/aversions for diets that are adequate/deficient in micronutrients in this way only after a trial-and-error period during which they sample a variety of diets offered to them (37,38). During this time, they learn to associate the nutrient quality of the diet with its particular smell, flavor, or appearance. The same mechanisms are likely to operate in relation to dietary macronutrients. Increasing the sensory qual-

ities and variety of these diets can lead to obesity in some strains of rats and may also be important for the maintenance of the obese state in humans (33). However, it is important to note that, while people obviously select what they like, this does not necessarily suggest that increasing the sensory quality or the variety of sensory attributes of a diet will lead to obesity. Recent evidence in humans suggests that increasing only the sensory variety of a nutritionally controlled diet leads to elevated energy intake over 7 days (39). The longer-term effects of changes in the sensory attributes of foods per se on energy balance are unknown. This may simply be due to the difficulty of conducting such an experiment. Sensory factors may interact with other factors such as diet composition or genetic predisposition to precipitate hyperphagia. Internal cues interact with sensory information to help formulate appropriate food (nutrient) selection or foraging strategies (33–37). Aspects of sensory experience have been rated by healthy, free-living adults among the top three determinants that guide their food detection and ingestion (40,41). Mattes (6) suggest that in the clinical setting where many environmental considerations are less prominent pathologically induced sensory disturbances can be important, particularly in affecting the acceptability of specific foods, e.g., clinical supplements.

#### **B Gastrointestinal Components**

The gut is known to have an important role to play in the short-term control of feeding behavior. It was initially believed that hunger sensations arose in the stomach (42). It is now accepted that a major role of the stomach is to regulate the flow of energy and nutrients into the small intestine. The stomach also places a physical constraint on the amount of food that can be consumed at a given meal. This fact has been applied, in extremis, during gastroplasty surgery as a means of obesity treatment. Stomach size adapts to the amount of food habitually eaten. This effect means that previously undernourished people have to eat small frequent meals, during the initial stage of nutritional rehabilitation, although as refeeding progresses, energy intakes can reach spectacular levels (30,43). Stretch and CCK receptors inform the CNS of the status of the stomach. The small intestine itself places a further constraint on the amount of food that can be ingested, since a certain time is taken to complete digestion and absorption. Both of these processes appear to be particularly important in releasing cascades of signals (hormones, peptides,

action potentials along gastrointestinal nerves) including the nutrients themselves to the postabsorptive circulation (44). It is interesting that patients with short intestines (and few secondary complications) attempt to eat to energy requirements. This means they are hyperphagic, presumably to compensate for the decreased absorptive capacity of the shortened small intestine (M. Elia, personal communication). In addition, stretch, CCK receptors and osmoreceptors, and a variety of gastrointestinal peptides all appear to play some role in affecting short-term feeding.

### C The Liver

The liver is the main organ that receives and deals with the digestion products of a meal, except for chylomicrons, which initially bypass the liver, since they are absorbed through the lymphatic system. It has been suggested that this effect contributes to the delayed effects of fat in suppressing appetite (32). It has been suggested from preference-conditioning experiments using portal infusions of fructose (45) that the liver also functions as a sensory organ. This is because rats learn to prefer flavors that are paired with a glucose infusion into the hepatic portal vein. The liver possesses extensive neural connections to the brain which appear to be involved in glucoprivic and lipoprivic feeding, at least in rodents (46). Pharmacological impairment of nutrient oxidation in the liver stimulates intake (47). A detailed discussion of these links between nutrient metabolism and the CNS is given below. The liver is the main site of assimilation, metabolism, and distribution of nutrients subsequent to ingestion. The liver is most likely the central organ that communicates information about peripheral fuel status to the brain (48).

### D Circulating Factors

The circulation and the peripheral nervous system together inform the brain of the overall status of energy and nutrients that are 1) in the circulation, 2) moving into the circulation from the gut (and hence indirectly of their concentration in the gut), and 3) available in nutrient stores. While the gut provides important cues which probably alert the brain to the likely influx of energy and nutrients, failure to reinforce this message by actual delivery of energy and nutrients will lead to diminished sensations of satiation and PI satiety. Thus, sham-feeding dogs (49) and rats are hyperphagic (50,51). On the other hand, nutrient infusions as lipid or glucose fail to elicit the same

degree of caloric compensation as oral loads of nutrients (52).

### E Monitoring of Energy and Nutrient Flux by the Nervous System

It is important to note that macronutrients exert important influences on appetite and energy intake (EI) at the preabsorptive level. These effects have been considered in detail elsewhere (6,44,53,54). Numerous models have been put forward to suggest that the stores of a single nutrient exert negative feedback on EI. These include the aminostatic (55), glucostatic (56), and lipostatic (57) hypotheses. Single nutrient based feedback models and their limitations have been described in previous discussions (see 3,58,59 for review). It is now apparent that models examining the effects of macronutrients on satiety should include the effects of all three macronutrients. Such integrative models explain a greater proportion of the variance in appetite and energy balance than single-nutrient feedback models (59).

A further development in the field of ingestive behavior in recent years has been the general acceptance that macronutrients exert multiple feedbacks on appetite and feeding behavior at the different levels of nutrient ingestion, digestion, absorption, assimilation, and metabolism (58,59). Furthermore, there is growing evidence that the major macronutrients protein, CHO, and fat simultaneously exert different effects on satiety at these different levels of organization (58,59). Thus, the effects of a given nutrient on appetite need to be considered, *inter alia*, in the context of (i) the presence or absence of other nutrients, (ii) the levels of physiological organization it operates at, and (iii) the metabolic state and EB profile of the subject concerned. There is now a growing body of evidence that suggests that in the fed state, increases in the oxidative disposal of recently ingested macronutrients correlate with satiety (6,7,49, 56–59). It has been suggested that nutrient oxidation in the liver influences hepatocyte membrane potentials (48). These changes apparently induce neuronal activity in vagal afferents connected to the mid-brain (48,58).

Conversely, it has been shown that specific agents that competitively block carbohydrate and fat oxidation (2-deoxyglucose and methylpalmitoxirate, respectively), increase food intake in rodents in a dose-dependent manner (60). 2-DG also increases hunger in man (61). The combined use of these metabolic inhibitors induces a massive emergency increase in food intake in rodents (60). These data suggest that when

the oxidation of one nutrient is blocked, other energy-providing nutrients can to some extent be used. However, inhibition of the oxidation of both major energy-providing macronutrients leads the rat to seek metabolic fuels from the environment (60). This in turn suggests that the CNS is responsive to the combined effects of macronutrient metabolism rather than being driven by negative feedback from a single nutrient.

What, then, are the combined effects of nutrient oxidation on appetite and subsequent feeding likely to be? As regards diet composition, nutrient processing, and peripheral signals related to feeding, there is now sufficient evidence to provisionally link changes in diet composition to changes in the signaling systems concerned with the control of macronutrient balance. This notion is schematically illustrated in Figure 5 and summarized as follows:

1. Changes in energy and nutrient intake can influence peripheral fuel selection (62–69).
2. Peripheral changes in fuel selection are determined by physiological and thermodynamic constraints which define a hierarchy in the immediacy with which the balance of recently ingested macronutrients are autoregulated by increases in their own oxidative disposal (protein > carbohydrate > fat) (3,11,58,59).
3. This hierarchy appears to parallel a hierarchy in the satiating efficiency of the macronutrients (3,58). Thus while protein, carbohydrate, and fat each contribute to satiety, they do so to differing degrees.
4. These two hierarchies may be causatively related since a growing body of literature suggests that nutrient oxidation in the periphery is monitored by the CNS as a component of satiety (46,60). In particular, Ritter and Calingasan have provided important evidence which suggests that neural pathways monitor fat oxidation in the periphery and CHO oxidation (perhaps more precisely) in both the periphery and the CNS (46). Currently less is known about protein oxidation, except that at the level of nutrient metabolism, protein is the most satiating macronutrient (58).
5. Langhans notes that the midbrain centers, concerned with monitoring peripheral fuel utilization, are connected via extensive neural relays to the areas of the forebrain (especially the hypothalamus and the paraventricular nucleus) that are the sites of action of peptide systems concerned with the control of protein, CHO, and fat balance (70).

Thus, an integrative model is beginning to emerge which may account for the manner in which the CNS is capable of monitoring physiological signals concerned with overall macronutrient intake and fuel flux (58–60). This model accounts for the manner in which feeding

behavior responds to changes in peripheral physiology and is illustrated in Figure 5. The CNS appears capable of monitoring overall fuel flux rather than responding to negative feedback from any single nutrient. In essence, feeding responses are coupled to physiological changes rather than being directly determined by them. The evolution of a flexible and adaptive system, concerned with the control of feeding behavior, is likely to have bestowed a far greater survival advantage on an opportunistic foraging species such as humans (or for that matter rodents) than a system in which behavior is an inevitable outcome of rigid physiological signals. Having considered how macronutrients and their metabolic fate influence feeding behavior, it is worth considering whether changes in macronutrient stores influence longer-term appetite and energy balance.

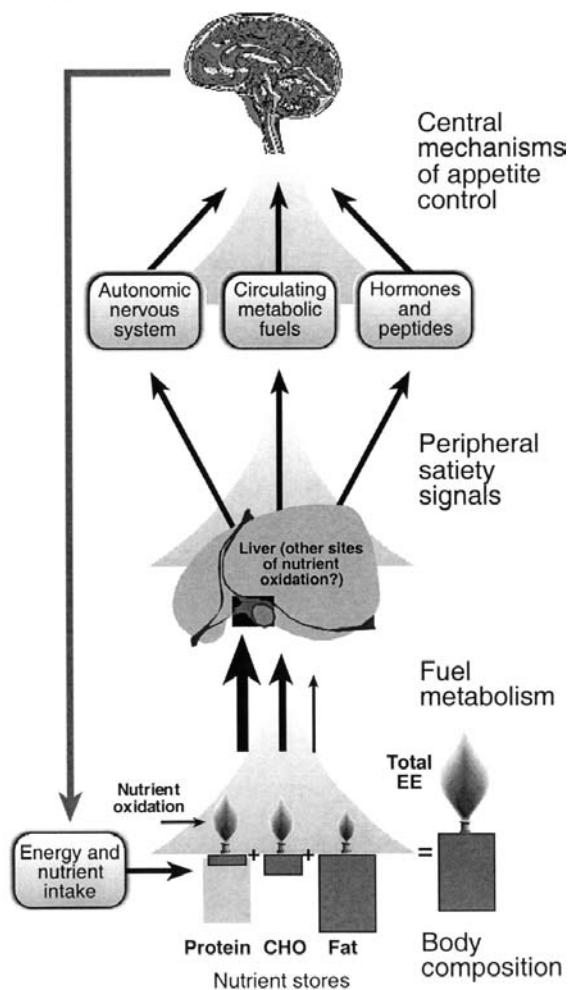

#### **F Do Nutrient Stores Exert Long-Term Feedback on Energy Balance?**

There has long been a belief that changes in macronutrient stores exert negative feedback on energy intake. It is interesting in this context that, despite the critical role of protein-energy relationships for survival time during under nutrition (30,68,69,71), few models have considered lean tissue changes as a major source of feedback signals that influence appetite control (see below).

Mayer proposed that peripheral CHO utilization exerts negative feedback on EI through the actions of hypothalamic glucosensors (22), which could be corrected by longer-term “lipostatic” regulation. In 1963, Russek postulated the presence of glucose receptors in the liver and formulated the hepatostatic theory of EB regulation (72). These receptors have never been localized, although it has recently been suggested that sensory vagal afferents function as hepatic glucosensors (48,70). Flatt proposed that CHO stores exert negative feedback on EI in 1987 (65). The robustness of these models has been reviewed elsewhere (58,59).

Kennedy in 1953 argued for feedback information reaching the hypothalamus from adipose tissue, which he presumed to be closely monitored in normal rats (57). The simplest way that such lipostasis could operate would be through the sensitivity of the hypothalamus to the concentration of circulating metabolites. Hervey in 1969 (73) proposed a mechanism for lipostatic regulation, based on endogenous measurement of the fat mass by means of a fat-soluble hormone. It was proposed that such a hormone would act as a physiological tracer that monitors adipose tissue mass by the dilution principle. Experiments in parabiotic rats (74,75) suggest

Linking diet composition to nutrient metabolism/stores and then to peripheral and central feeding signals

**Figure 5** Schematic diagram illustrating putative connections between diet composition, fuel metabolism, peripheral satiety signals, and central control of feeding. Diet composition affects satiety. Protein is more satiating than carbohydrate, which is more satiating than fat. Diet composition also affects postingestive fuel metabolism, since increases in protein and carbohydrate, but not fat balance, are tightly modulated by autoregulatory increases in their oxidative disposal. It is known that nutrient oxidation in peripheral tissues appears to be associated with satiety. The hierarchical regulation of macronutrient balance by oxidative disposal may partially underlie the hierarchy in the satiating efficiency of the macronutrients. Indeed, high levels of protein and carbohydrate (but not fat) oxidation are indicative of the fed state. High rates of fat oxidation are usually synonymous with energy deficits. It has also been suggested that changes in peripheral fuel metabolism may act as and trigger additional peripheral satiety signals that are relayed to feeding centers of the brain believed to be concerned with the control of macronutrient balance.

there is an exchange of some bloodborne factors between lean and obese animals that affects the food intake of the lean rat.

Similar experiments in the late 1970s using genetically obese rodents (76) created the conceptual context for the studies that have led to the identification of the protein leptin (77). Since the discovery of leptin in 1994, there has been an intense focus on signals from adipose tissue as key controllers of longer-term energy balance. The importance of leptin should not be underplayed. However, the strength of negative feedback arising from adipose tissue in humans should not be overestimated. It is abundantly clear from the current prevalence of overweight and obesity (15) that adipose tissue accumulation does not exert strong negative feedback which restores energy balance, at least from the point of excess EI. There is far more evidence that loss of adipose tissue leads to its regain. For instance, the majority of people who lose weight eventually regain it (78). There is now an extensive literature on leptin and other putative feedback signals arising from adipose tissue (see 79 for a recent review). There is a minuscule literature on the extent to which changes in adipose tissue exert feedback on appetite and energy intake at the whole body level. Neither the metabolism nor size of storage of any single nutrient per se exerts a powerful unconditioned negative feedback on quantitative feeding behavior (3,4,11,14). It is therefore important to examine how changes in nutrient stores and metabolism collectively influence appetite and energy balance, longitudinally under conditions where specific components of energy balance have been perturbed. It is critical that putative physiological and molecular mechanisms of appetite control should be related where possible to the actual feeding behavior they are supposed to influence. In this context it is useful to consider the value of underfeeding studies as a means of assessing the relationship between tissue loss and subsequent feeding behavior.

As regards disturbances of this system in the development of obesity, the evidence from the human literature suggests the following.

1. In the short term, it is remarkably easy to perturb energy balance in either a positive or a negative direction. Modifications of the composition or energy density of the diet can be used to generate considerable energy imbalances (3,4,14).

2. In the medium to longer term, the evidence suggests that humans defend against induced energy deficits, regardless of body weight at the outset of the induced deficit (15,78). Over the same time window, humans are remarkably tolerant of moderate increases

in energy balance. Thus American adults on average gain 0.2–2.0 kg per year (80).

3. While tolerant of excess energy balances, humans do not eat anywhere near the maximum levels of energy intake that are readily obtainable by selecting certain foods available in the Western diet. This behavior is apparent in certain pathological states such as binge eating, where intakes of up to 30 MJ/day have been reported (4).

4. It therefore seems that there is a tonic control on energy intake, which limits a very rapid weight gain in most people. There is little evidence that such tonic control operates via negative feedback loops, as for tightly regulated physiological systems. In other words, there is little evidence that, as fat mass accumulates, physiological signals become stronger and limit further gain in fat mass (81). The exact nature and strength of the mechanisms that restrain excess energy intake in humans are unclear.

5. There is greater evidence that energy deficits do induce signals that elevate appetite and energy intake. As weight loss proceeds, these signals appear to become stronger, until they become the primarily motivational forces governing an individual's behavior (82). There are a number of signaling systems in the periphery that interlink with the peptide messenger systems of the brain to increase intake when energy deficits significantly deplete tissue stores (83). The extent to which these systems are involved in the control of day-to-day feeding behavior in humans is less clear.

6. As regards depletion of body tissues during periods of energy deficit, most research has focused almost exclusively on fat (83) despite the fact that in the clinical setting a negative nitrogen balance and loss of lean tissue are known to compromise physiological function. Loss of lean tissue during therapeutic weight loss may be a major factor which signals to the brain that physiological integrity is being eroded. The signals are as yet unknown.

To explore the system determining human feeding behavior, it is appropriate to consider how central features and components of that system change under different environmental conditions. The most central feature of feeding behavior is food. Food varies in orosensory qualities and in composition. Until recently the orosensory qualities of foods acted as reliable cues that gave accurate information about the nutrient content of food and the physiological consequences of ingesting it. A growing number of advances in food technology have changed this relationship between the sensory attributes of the diet and its nutrient composi-

**Figure 6** Primary ways in which food and nutrient ingestion influences the main compartments of the human appetite system. Food influences this system through multiple feedbacks at multiple levels which can be traced through the processes of food location, ingestion, digestion, absorption, and metabolism. Satiety is therefore maintained by a functional sequence or cascade of sequential physiological events which reinforce each other. Removing parts of a food or nutrient's effects on this sequence will therefore diminish its impact on satiety.

tion. Figure 6 summarizes the main ways in which food can affect this feeding system.

## V DIET COMPOSITION AND FEEDING BEHAVIOR

Given the current prevalence of obesity worldwide and the role of overconsumption in generating a positive energy balance which is converted into weight gain, it is important to consider the composition of foods which form the basis of overconsumption. In turn, this introduces the key concept of diet composition and feeding behavior. How do the relative amounts of the energy-yielding macronutrients influence the control of food intake? There is a good deal of variation in the experimental results from research on this issue, and findings have purported to show inter alia that all macronutrients have equal power to suppress subsequent energy intake, protein exerts a greater suppressive effect on subsequent energy intake than carbohydrate or fat, carbohydrate and fat have similar effects on caloric suppression, fat generates strong signals which suppress appetite, and fat is the least effective of the macronutrients at suppressing appetite.

### A Macronutrients, Satiety, and PI Satiety

#### 1 Protein

Protein appears to be the macronutrient which suppresses energy intake to a greater extent than any of the other macronutrients. Careful retrospective analysis of food records (14,84) indicate that protein exerts post-ingestive action over and above the contribution from energy per se. In studies where subjects record their food intake, the percentage energy intake from protein has been found to predict decreases in intake. Percent energy intake from fat is a significant predictor of increase in energy intake and carbohydrate is very weakly related to energy intake. (14,84,85).

Protein also exerts a large influence on satiety in the laboratory. Some studies using pure macronutrient loads delivered to the stomach or solutions quickly swallowed by subjects wearing noseclips (86,87) have found that all macronutrients have equal satiating power. It is intriguing in this regard that sensory cues (especially taste) may be important in clearly identifying the effects of nutrient ingestion. Miller and Teates (88) found that male Sprague-Dawley rats were able to select from nutritionally different diets in a way that stabilized the protein

energy ratio at 0.14. However, when rats were subjected to impairment of oral somatosensory input, they were unable to maintain a stable selection pattern. The authors hypothesized that selection between protein and carbohydrate (or energy) at least “involves an associative learning process in which somatosensory inputs effect feeding activity and/or the properties of the food link dietary choice behaviour to later metabolic consequences.”

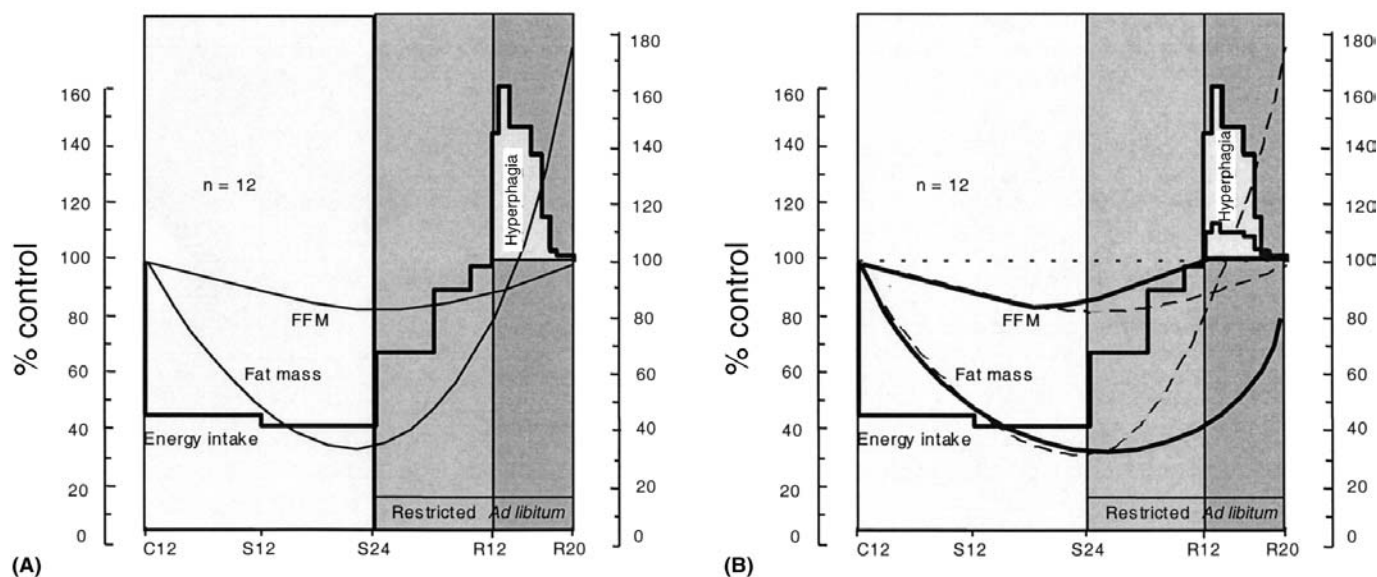

It also appears that there may be a critical threshold in the amount of protein required to suppress subsequent energy intake since studies that have found little effect of protein relative to other macronutrient preloads have only used small amounts of energy as protein in the preload (86,89). Hill and Blundell (90) found that a high-protein (HP) meal (31% of 2.1 MJ) produced a greater sensation of fullness and a decreased desire to eat, relative to a high-carbohydrate (HC) meal (52%) of the same energy content. Hill and Blundell (91) also found that both obese and normal-weight subjects reduced their subsequent meal intakes by 19% and 22% respectively after a HP (54% of 2 MJ) meal compared to a HC meal (63% of 2 MJ) with weight of food held constant. Barkeling et al. (92) gave 20 normal-weight women a high-protein (43% of 2.6 MJ) or a high-carbohydrate (69% of 2.6 MJ) lunch and measured the energy intake at a subsequent evening meal. They found that energy intake was depressed by 12% after consumption of the HP meal. Booth et al. (93) also found that an HP meal reduced the intake of a subsequent test meal by 26% relative to a virtually protein-free meal in normal-weight individuals. Thus, protein appears to be particularly satiating when given at moderate and large amounts.

This apparent appetite-restraining effect of protein has not yet been given a strong theoretical basis, and there has been little recent investigation of the “protein-stat.” It is perhaps pertinent to note that essential amino acids when ingested in excess of requirements form a physiological stress that must be disposed of by oxidation. It is known that animals will alter feeding behavior in order to alleviate a physiological stress (94). Pigs, in particular, appear capable of learning to select a protein:energy ratio in the diet that is optimal for growth (95,96), as can rats (88). There is also evidence that the kind of amino acids ingested may influence satiety. Imbalances in single essential amino acids can greatly affect the feeding behavior of rats (97). The protein:energy ratio of foods may be important in influencing feeding. Malnourished children find it difficult to tolerate nutritional supplements whose protein:energy ratio is too high. Millward has hypothesized that lean tissue

deposition may be an important factor driving appetite during catchup growth in children (98).

Stubbs and Elia have recently suggested that lean tissue depletion during weight loss may be at least as important as adipose tissue depletion in increasing appetite and driving intake upward (99). This concept has been long neglected. One seminal study has enabled the relationship between tissue loss and subsequent feeding behavior to be determined (30). The results were quite remarkable and have recently been revisited by Dulloo (100,101). During the Minnesota semistarvation study a group of lean men were chronically underfed for 24 weeks, consuming ~40% of their normal EI throughout this period. During this time they lost ~70% of their fat mass and ~18–20% of their lean body mass. For the next 12 weeks, they were incrementally re-fed in a mandatory manner. By the end of this period, they were still in a deficit of ~25% for fat mass and 12–15% for lean body mass. During the final 8 weeks subjects had *ad libitum* access to a range of foods. During this period energy intake initially increased to 160% of requirements and gradually subsided to pre-weight loss levels. However, by this time fat mass had reached 170% of pre-weight loss values, while lean body mass had returned to pre-weight loss levels (99,100). These relationships are depicted in Figure 7A. Thus the cessation of post-weight loss hyperphagia coincided with a massive overshoot of fat mass, but precise repletion of lean body mass. There are very few datasets of this quality available, which highlights the importance of conducting more detailed longitudinal studies with this degree of precision and accuracy. If depletion of lean tissue during weight loss stimulates hunger, then increased protein intake, subsequent to significant weight loss, may replete lean tissue faster and help stabilize body weight at a new, lower level. This hypothesis is currently under test. The concept is illustrated in Figure 7B.

It can be seen from the arguments outlined in this discussion that the physiological regulation of lean tissue may be a critical factor which exerts feedback on subsequent EI. When subjects are in energy balance, excess protein intake does not increase the size of lean body mass (69). Instead, it is disposed of by transamination, deamination, and urea production. This regulation of protein balance by obligatory oxidative disposal predicts a suppression of subsequent energy intake (11). During undernutrition, lean body mass becomes depleted (30,68,69). The Keys data from the Minnesota semistarvation study suggest that when food is available *ad libitum*, subjects do not stop eating when fat mass is repleted but when

**Figure 7** (A) Relationship between energy intake and tissue change during 6 months' severe undernutrition, 3 months' rehabilitation, and 2 months' ad libitum feeding in 12 of the subjects who took part in the Minnesota study. Of particular note is the fact that ad libitum energy intake returned to preunderfeeding levels at approximately the time lean tissue returned to baseline values. By this time fat mass had overshoot baseline and reached ~170% of original levels. (B) predicted effects of protein supplementation on the relationship between tissue deposition and post-weight loss hyperphagia. Depletion of lean tissue may act as a signal for hyperphagia once original fat mass has been repleted. Dietary protein supplements, after weight loss, may help replete lean tissue more rapidly, diminish post-weight loss hyperphagia, and promote weight stability below pre-weight loss levels.

lean body mass is repleted. Thus there is evidence that the regulation of lean tissue (which helps maintain normal physiological function), through oxidation of excess and repletion of deficits in protein intake, may exert some negative feedback effect on longer-term energy intake (99). The role of lean tissue in this respect has been largely ignored. It is important to understand how both lean and adipose tissue changes relate to longer-term energy balance (30,99–101). This is again important in the clinical setting since loss of lean tissue in disease compromises physiological function and can complicate further the effects of disease. Understanding how loss of fat and lean tissue relate to other aspects of function, health, and well-being will be critical in improving sustained weight loss.

## 2 Carbohydrates

The public perception of carbohydrates has oscillated in recent decades. Throughout the 1970s there was a tendency for a number of nutritionists to view carbohydrates (especially refined forms) as conducive to weight gain. This reached its logical extreme with

perceptions of sugars as “pure, white, and deadly” by Yudkin (102). Since that time the nutritional perception of carbohydrates has improved dramatically. By the mid-1990s, dietary fat had developed a reputation of near demonic proportions as the dietary villain of the late 20th century and was squarely blamed as the major dietary constituent promoting excess EI. During this time, dietary CHO was generally viewed in generic terms as a beneficial nutrient whose ingestion could promote all manner of positive outcomes with reference to weight control (103). The positive effects of carbohydrates on energy balance were enshrined in the predictions of Flatt's glycogenostatic model of energy balance control. The general perceptions about carbohydrates and energy balance at this time were as follows:

1. It was generally accepted that carbohydrates are absorbed, metabolized, and stored with less bioenergetic efficiency than dietary fat and, per MJ of energy ingested, were protective against weight gain. Indeed, a general perception was developing that because *de novo* lipogenesis appears limited when humans feed on Western diets, that carbohydrate ingestion does not promote fat storage (104,105).

2. At the same time, there was a renaissance of interest in carbohydrate-specific models of feeding. The notion that carbohydrate metabolism or stores exert powerful negative feedback on EI became quite firmly established in the field of energy and nutrient balance (59,81).

3. The simultaneous focus of researchers and health professionals on dietary fat as the pivotal nutrient promoting high levels of EI reinforced carbohydrate-specific models of feeding. HF hyperphagia was seen as due to the tendency for subjects to eat to carbohydrate balance rather than energy balance. Thus hyperphagia on high-fat (HF) diets (which are by definition low in the percentage of energy from carbohydrate) was seen as being driven by the need to ingest a certain level of carbohydrate (59,81).

4. By the same reasoning, diets high in carbohydrates were deemed to be more satiating, specifically because they were high in carbohydrates.

5. The extension of this logic led to the notion among some that it was difficult if not virtually impossible to overeat on a high-carbohydrate diet (104,105).

6. Finally, epidemiological observations have shown that, in subjects recording their food intakes, the percentage of EI from fat and carbohydrates are reciprocally related to each other. One form of this relationship has been termed the fat-sugar seesaw. It has been noted in one seminal study that high-sugar consumers also tend to be thinner than HF consumers are (106). This led to the suggestion that sugar displaces fat energy from the diet, and since fat is conducive to weight gain, high sugar intakes may well protect against obesity (107).

Carbohydrates had never had it so good. These messages percolated through the scientific community to governments, consumers, and industry who were (and still are) deeply concerned about diet-induced obesity in developed and developing countries. Fat reduction became the order of the day and the low-fat (LF) food market rapidly expanded (108,109). The fat reduction message has now become so strong that consumers appear to have focused on fat avoidance as a primary nutritional objective while foraging for food in local supermarkets. The food industry has gone to great lengths to diversify products in the direction of LF, lower-fat, and high-carbohydrate foods, which have sufficient sensory appeal that consumers will continue to select and ingest them. A major sensory attribute of high-carbohydrate foods, which is almost ubiquitously appealing, is sweetness.

In recent years, there have been some doubts about the paramount role of carbohydrates as the central

nutrient around which energy balance is regulated and body weight controlled (59,81):

1. While there is evidence that excess carbohydrate is stored with less efficiency than fat, the relevance of these effects to free-living Western consumers has been questioned.

2. Several rigorous tests of carbohydrate specific models of feeding have suggested that carbohydrate oxidation or stores per se do not exert such powerful unconditioned negative feedback on EI (14,59,81,110). Rather, as macronutrients come in the diet (where fat is disproportionately energy dense), there appears to be a hierarchy in the satiating efficiency of the macronutrients protein, carbohydrate, and fat. Per MJ of energy ingested, protein induces supercaloric compensation, carbohydrate generates approximately caloric compensation, and fat precipitates subcaloric compensation, and hence often excess EI. Furthermore, simple statistical modeling has shown that models that include all three macronutrients explain far more of the variance in EI, either in the laboratory or among free-living subjects recording their own intakes (14). When energy density (ED) is controlled, protein is still far more satiating than carbohydrates or fats (at least when ingested in excess of 1–1.5 MJ loads). Under these conditions, differences in the satiating efficiency of carbohydrates and fats become more subtle (4,14,59) (see below).

3. HF hyperphagia can be explained by the high palatability and ED of HF foods (which facilitate greater levels of intake) and the low postabsorptive satiety value of fat (which prevents subsequent compensatory decreases in EI). While carbohydrate is more satiating than fat, excess fat intake is not necessarily driven by a need to eat to maintain carbohydrate balance.

4. There appear to be several reasons why many high-carbohydrate foods are more satiating than HF foods. First, they are usually (but not always) less energy dense than HF foods. Many high-carbohydrate foods contain dietary fiber, which limits rates of ingestion and digestion, both of which can have a limiting effect on EI. High-carbohydrate foods that are dry will tend to exert a higher osmotic load in the gut than will HF foods of similar moisture content. When the energy content and ED of high-carbohydrate and HF foods are controlled, readily assimilated carbohydrate is more satiating than fat. This difference in the satiating capacity of fat and carbohydrate can be deemed to be independent of ED or palatability. However, this effect is weaker than when HF, ED foods are compared to lower fat, less ED foods that are high in carbohydrate (103). Thus, the nutrient-specific differences in the sati-

ating effects of fats and carbohydrates need to be considered in relation to the structure and composition of the foods in which those nutrients abound (103).

5. It has frequently been stated that there is no evidence that foods high in carbohydrates promote overconsumption. This may be due to the fact that the majority of studies examining the effects of high carbohydrate and HF foods on feeding behavior, compared HF, more energy-dense foods to high-carbohydrate (LF) less energy-dense foods. The majority of studies that demonstrate the effects of fat in promoting excess EI examined how adding fat to the diet influences feeding. Very few studies have examined how *adding* carbohydrates to food affects feeding behavior or EI (103). In one study at least, increasing the ED of the diet by dramatically increasing the maltodextrin content, led to marked elevations of EI over 14 days (110).

6. While the fat-sugar seesaw has become a well-recognized phenomenon, the phenomenon itself has been harder to pin down. That fat and sugar or even fat and carbohydrate are reciprocally related to each other in the diet is almost inevitable, given that they are the main energy providing macronutrients. Indeed, we have found a strong fat-sugar seesaw in 1032 ready-to-eat foods taken from the British food tables. Gram for gram, the reciprocal relationship between fat and carbohydrate (or fat and sugar) is far less evident (4).

There is very little known about the vast range of different starches and their various structures in relation to appetite and energy balance (103). These are still uncharted landscapes on the research horizon. The foods most capable of limiting EI (both voluntary and metabolizable) are those rich in unavailable complex carbohydrates. However, there is a catch, because in general humans are not too fond of these foods, and as typified by the average Western diet, when given the choice they tend to select a diet comprising 37–42% fat, 10–20% sugar, and a variable amount of high glycemic index starches. The average Western adult's fiber intake is spectacularly low.

The evidence relating to the glycemic index of carbohydrates cannot be interpreted owing to the heterogeneity of study designs, vehicles and treatments used, and indeed doubts as to whether the glycemic index of food is a physiological constant. This should be an area of future research. Given the range of CHO structures available to the food market and the different physicochemical properties they possess, it is particularly important to identify how these potentially beneficial effects of CHO structure

can be used to enhance preabsorptive and absorptive phase satiety signals.

### 3 Fat

Numerous laboratory studies have now shown that when humans or animals are allowed to feed ad libitum on high-fat, energy-dense diets, they consume similar amounts (weight) of food but more energy (which is usually accompanied by weight gain) than when they feed ad libitum on lower-fat, less energy-dense diets (9–11). The ingestion of systematically manipulated HF, energy-dense diets does not appear to elicit compensatory feeding responses. Interestingly, if single midday meals are covertly manipulated, by increasing or decreasing their energy density using fat or carbohydrate, under conditions where subjects feed on range of familiar food items, compensation appears to be more precise (111,112). When experiments are conducted over similar time frames but the diet is systematically manipulated (i.e., subjects cannot select food items of differing compositions), compensation for the fat content of the diet is again poor (113). These observations further suggest that both learning and preabsorptive and absorptive-phase factors play a major role in meal to meal compensation. Furthermore, a number of prospective observational epidemiological studies show that fat consumption is a risk factor for subsequent weight gain (114). However, it is not likely to be the only risk factor, and few analyses take account of how fat may interact with other types of carbohydrates. For instance, in the short term, sweet high-fat foods have potent effect at stimulating energy intake.

We are beginning to gain insights into the effects of types of fat on appetite control, owing to the search for forms of fat which do not predispose the general population to weight gain. Fat structure varies in terms of (i) chain length, (ii) degree of saturation, (iii) degree of esterification, and (iv) by combining (i–iii), through the development of novel structured lipids. Data are scarce and fragmentary in this area, but some provisional patterns are beginning to emerge. Substitution of long-chain triglyceride (LCT) for medium-chain triglyceride (MCT) limits the high levels of energy intake that usually occurs when animals or humans ingest high-fat, energy-dense diets (115). However, very large doses of MCT are required in order to achieve these effects. MCTs may suppress appetite relative to LCT as they are more readily absorbed and oxidised. There are

few data on whether short-chain fatty acids inhibit appetite in nonruminants. There is some preliminary evidence that ketone bodies (specifically beta-hydroxybutyrate) are appetite suppressants when given orally (116), and this may enhance compliance when subjects attempt to lose weight using very low calorie diets. Currently there is little evidence that degree of fatty acid esterification influences appetite and EI (117,118).

It has been suggested that polyunsaturates (PUFAs) are protective against obesity since they are more readily mobilized and oxidized and may influence gene expression of appetite-controlling peptides (119). Recent work in humans suggests that saturated fats are less satiating than mono- or polyunsaturates (120,121). An intriguing study in humans has reported that supplementation with very high levels of gamma-linolenate (at 5 g/d compared to 5 g/d olive oil) significantly reduced weight gain over 12 months after extensive weight reduction using very low calorie diets (122). Currently there are few or no reports on the effects of structured lipids on appetite and energy balance. However, it can be envisaged that structured lipids could be developed to combine some of the individually modest effects of fat type on appetite and feeding behavior. In the future, specific nutrients could be tailored to exert quantitatively significant effects on appetite control, tissue deposition, and energy balance. In this context it is of note that certain isomers of CLA can be used to influence appetite and tissue disposition in animals (123) and perhaps humans (124). The effects of conjugated linoleic acid (CLA) are not entirely understood but appear to be near pharmacological in nature.

#### 4 The Fat Paradox

The apparently ambivalent effects of fat have generated a phenomenon referred to as the fat paradox. On the one hand, a fat such as corn oil infused into the jejunum has been shown to slow gastric emptying, increase feelings of fullness, and reduce food intake in a test meal. Infusions into the ileum bring about similar effects and also reduce feelings of hunger (125). On the other hand, similar infusions made intravenously exerted no effect on gastric emptying or measures of appetite. Lipid infusions at ~80% of resting energy requirements, over 3 days, produce only partial compensation (43%) of energy intake (126). Similar experiments have been carried out in rats where intraduodenal infusions inhibited food intake whilst intravenous infusions did not (127). These findings imply that, after the ingestion of fat,

potent fat-induced satiety signals are generated by preabsorptive rather than postabsorptive physiological responses. In addition, a number of studies of short- and medium-term duration have demonstrated the existence of high intakes of energy with high-fat foods (9–11). How can these two features be reconciled? It appears that, in normal feeding, the stomach controls the rate at which nutrients are delivered to the duodenum, on an approximately caloric basis. Thus, the high levels of satiety seen in gastrointestinal infusions studies may well be due to supraphysiological saturation of satiety mechanisms arising from the small intestine.

#### 5 Combined Effects of Macronutrients and Energy Density on Energy Intake

There has recently been a considerable debate as to whether the effects of diet composition on energy intake can be simply explained in terms of dietary energy density. Energy density should be defined in terms of the metabolizable energy per unit weight of ready to eat food. The major determinants of dietary energy density are water and fat, with water having the greatest effect. In general, the energy density of ready to eat foods is largely determined by a fat-water seesaw, with energy density falling as the water content of food rises and as the fat content of food falls. Protein and carbohydrate contribute relatively little to dietary energy density. There is considerable scope for technological developments that can alter the energy density of foods without compromising palatability. This is a major research challenge for the food industry (14).

At the present time, studies of energy density and energy intake are biased in favor of short-term interventions or longer studies where the composition of the diet is systematically altered (14). There are far fewer data from more naturalistic environments. These biases in the literature have led to an impression that energy density exerts powerful if not overriding deterministic effects on EI. Longer-term interventions are urgently needed.

As foods occur in real life, there is a hierarchy in the satiating efficiency of the macronutrients (see above discussion). The main effect of controlling energy density is to diminish the impact of differences in the satiating effects of fat and carbohydrate. Energy density exerts profound effects in constraining energy intake in short- to medium-term studies. Subjects behave differently in longer-term interventions. Energy density is a factor that at high levels can

facilitate excess EI, and at low levels constrains EI (14). However, the effects that dietary energy density may exert on appetite and EI should be considered in the context of other nutritional and nonnutritional determinants of EI rather than as a substitute for those considerations.

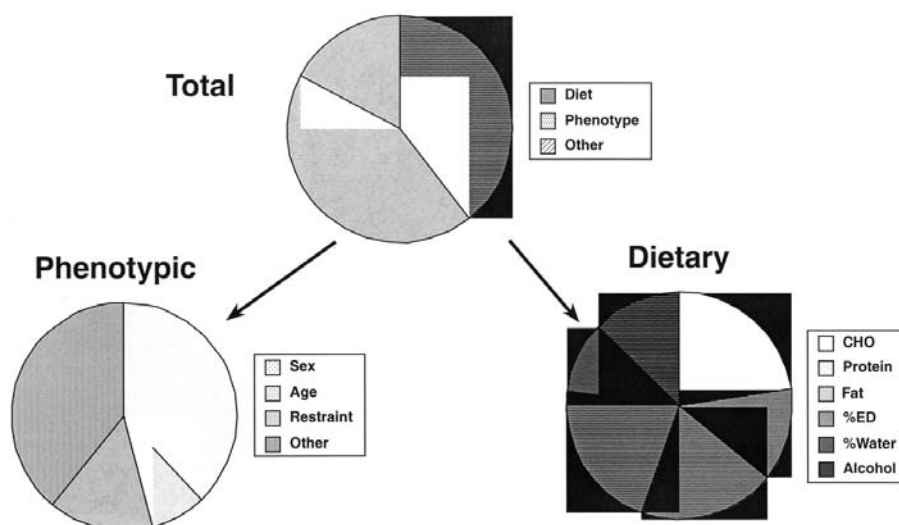

In considering the nutritional determinants of EI in 102 free-living adults recording their food intake for 7 days, both macronutrients *and* energy density determine energy intake (14). The notion that energy density alone drives energy intake is oversimplified. Multifactor models appear more appropriate to explain nutritional determinants of feeding. This is illustrated in Figure 8. It is recommended that modeling work such as this be extended in order to better appreciate and predict the way in which the nutritional characteristics of the diet affect energy intake in people at large. Since differences between subjects can account for almost half of the variance in the relationships between food composition and energy intake (Fig. 8), models should help to identify key factors that predict a significant proportion of intersubject variation in feeding behaviour.

Drewnowski has provided evidence that energy density affects the sensory stimulation to eat (128). People tend to prefer more energy-dense foods. The implications this has for appetite control are unclear but it is

our opinion that EI does not simply vary as a function of the energy density of the diet. We urgently need to understand how different types of people respond to changes in dietary energy density in the real world. The implications for consumers are that increasing consumption of foods lower in energy density may protect against weight gain but is unlikely to induce any spontaneous weight loss in subjects not attempting to control their weight. Furthermore, people appear to prefer more ED foods and so are likely to continue to select them (14,128). Psychological and possibly physiological disposition of the subjects will greatly affect their preference for and response to the energy density of foods.

## 6 Micronutrients

There are very few data on the effect of micronutrients on feeding behavior and body weight under normal feeding conditions. There is evidence that rodents will learn to select a diet whose ingestion will alleviate a micronutrient deficiency (38,94). It may also be supposed that the administration of a micronutrient that will, for instance, improve a deficiency-related defect in nutrient metabolism, will improve appetite for that nutrient, and perhaps appetite in general.

**Figure 8** Pie charts illustrating the percentage of the variability in energy intake ascribable to different sources in 102 subjects recording their food intake for 7 consecutive days. Approximately 39% of the variability was due to diet and ~40% was due to intersubject variability. These two major sources of variation are subdivided further. These charts clearly illustrate that the determinants of energy intake in human adults are multifactorial.

## B Issues Concerning Satiety Signals

Two further issues can be envisaged which are important and still to be resolved.

### 1 Postabsorptive Satiety

The pattern of food intake and the physiological events that occur at the end of a meal indicate an important role for preabsorptive signals in terminating eating and in determining the episodic nature of eating. What role is played by postabsorptive processes? The energy (fuel) balance approach to appetite control is based on the idea that the metabolic fate of nutrients in the body exerts important influences over behavior (65). Some hypotheses, such as the idea of linking food selection to serotonergic activity (129), are based exclusively on the understanding that nutrient-induced metabolic activity exerts a directional influence on food consumption. However, some recent studies have indicated that large differences in the oxidation patterns of nutrients (fat and carbohydrate) can occur (after dietary manipulations) which do not appear to exert any influence over the quantitative aspect of food intake (130) at least for the following 24 hr. The same group has provided evidence that nutrient metabolism does exert potential influences on energy intake when these relationships are examined over a number of days (11). Logic demands that the requirement for nutrients by the body will exert an influence over the form of behavior that provides these nutrients, but what is the evidence for this, what is the nature of the mechanism involved, and what are the physiological limits within which the mechanism operates? Postabsorptive signals are probably far more effective at stimulating hunger during negative energy balance than they are at elevating satiety in the fed state. That is, tissue depletion during negative energy balance may exert a far greater physiological feedback on appetite than does tissue deposition during periods of positive energy balance.

Some studies have suggested that the rate of oxidation of fat and carbohydrate exerts an inhibitory effect on appetite (46–48,60). Specific proposals have been made by Langhans and Scharrer (48) regarding the increase in intracellular metabolism in hepatocytes. Some of this evidence is indirect. The most potent evidence relates to physiologically induced nutrient “deficits.” The blockade of glucose oxidation by 2-DG or 2,5-AM (47) or fat oxidation by methyl-palmoxirate or 2-mercapto acetate leads to an increase in food intake in animals (46–48,60). These phenomena have been termed glucoprivic and lipo-

privic forms of feeding. These effects are strong phenomena in animals [and for 2-DG, in humans (85)] and form the basis for useful experimental models; their respective pathways through the brain can be traced by lesioning or biochemical procedures. This work by Ritter's group is extremely important since it indicates the neurochemical processing of metabolic activity (46).

Thus, decreases in nutrient oxidation appear to stimulate intake. Evidence that increases in nutrient oxidation comprise part of satiety are less direct. Considering carbohydrate metabolism, experimental results of Astrup and Raben indicate an extremely high correlation ( $r = .9$ ) between hunger and postingestive measures of carbohydrate oxidation, AUC plasma glucose, insulin, and norepinephrine (24,104). Stubbs et al. (11) have also found statistically significant negative relationships between protein and carbohydrate stores and oxidation and the subsequent day's food intake, in normal men living in a calorimeter for 7 days at a time. The same relationships were significant for fat oxidation but not stores. Stubbs et al. (11) have interpreted these data as suggesting that the regulation of nutrient stores by increases in oxidation may partly underlie the greater capacity of protein and carbohydrate to suppress subsequent intake.

A key question here is whether or not the different profiles of nutrient oxidation arising from variations in the diet composition exert an influence over eating behavior. From a biological perspective, an animal could deal with extreme forms of diet composition through metabolic adaptation—with no consequences for behavior. There is unlikely to be any obligatory requirement to adjust behavior unless the process of metabolic adaptation incurs a physiological stress or strong benefit. It therefore seems important to establish the conditions under which nutrient-induced metabolic activity exerts either a quantitative or directional influence over eating behavior and whether it is possible to condition these effects. It seems reasonable to hypothesize that under conditions where prior learning cues are removed and extremes of metabolic adaptation are reached, then feeding behavior will be altered. Feeding behavior may subsequently be altered before such extremes are reached if the metabolic change is a cue for learning. Since the majority of Western adults are now overweight and obese, few satiety signals appear effective enough to restrain our inherent mammalian tendency to gain weight, when the environment permits.

In addition, it is possible that metabolic (postabsorptive) events only achieve biological relevance if they are

accompanied (preceded) by preabsorptive signals. This would indicate that appetite control is achieved jointly by physiological responses generated at different stages in the handling of nutrients following ingestion. The organism presumably recognizes these physiological changes as sequential cues that, by reinforcing each other, cumulatively constitute the “satiety cascade” (131). Removing individual cues from the sequence may well weaken the overall impact of a food or nutrient on satiation or PI satiety.

### C Specific Macronutrient Selection in Humans?

It is clear that human beings display preferences for, and selection of, different types of foods. These foods vary in taste, texture, energy density, and nutrient composition together with a host of cognitively mediated attributes. Under extreme physiological circumstances, animals and presumably humans can display a strong preference for a dietary component that is in deficit. The literature on salt appetite and on preferences of vitamin-deficient animals for foods that alleviate the deficiency are examples of this (see 94 for an introductory discussion of these phenomena). Nutrient deficits are not a necessary condition of a physiologically induced preference or aversion. To what extent can humans display a preference or aversion toward a particular macronutrient? What is the mechanism that could mediate this form of behavior? It is likely that a nutrient-based preference could develop through a process of learning. This would need a clearly defined unconditioned signal (arising from the physiological system)—a detection mechanism—linked to a particular sensory or environmental cue. For instance, rats learn to prefer flavors that are associated with fructose infusions into the portal vein (32,45). These phenomena are most likely to be best observed under conditions where a learned change in feeding behavior will alleviate some physiological stress. The metabolic handling of protein loads constitutes a greater physiological stress than the oxidation/storage of fat or carbohydrate. Under experimental conditions, a number of animal species adopt selection strategies to optimize the protein:energy ratio of their diet and avoid an intake of excess protein (32,94,95).

It is worth considering whether there is any other unconditioned physiological signal that could serve as the source of food-selecting behavior directed to a particular macronutrient under more naturalistic conditions. For instance, athletes tend to consume greater amounts of carbohydrates than the general population. Is any of this selection driven by physiological

changes induced by exercise per se? The organoleptic properties of the diet may influence nutrient selection for nonphysiological reasons. It is also important to bear in mind that selection of foods can be influenced by a number of non-physiological- and non-sensory-associated factors. Examining the relative and quantitative importance of physiological versus nonphysiological determinants remains an important area for future investigation.

### D Macronutrients, Appetite, and Obesity

#### 1 Food and Macronutrient Intake in the Etiology of Obesity

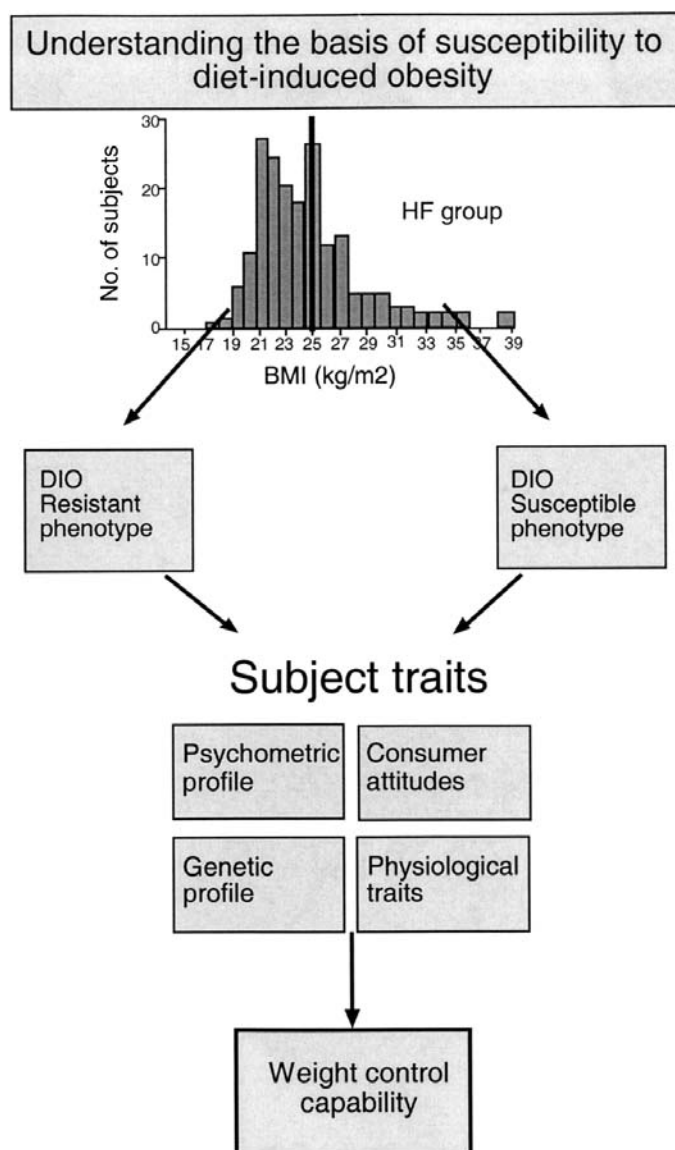

Considerable attention has recently focused on the issue of how the macronutrient composition of the diet can influence the current epidemic of obesity in western society (3,4,15). Ingestion of dietary fat does appear to be a risk factor for subsequent weight gain (114), although it is possible to become obese on a high-carbohydrate diet (132). In particular, certain types of carbohydrates may interact with fat to facilitate higher levels of intake. Drenowski et al. and Mela et al. (133,134) have produced data that suggest that fatter people prefer fattier foods. There is not a great deal of direct evidence that preference per se will influence quantitative intake (i.e., how much food is eaten) to an extent that will influence body weight. It is, however, very likely that preference influences qualitative food intake—i.e., what foods are eaten. This is important because the phenomenon of passive overconsumption of energy on high-fat diets is not an issue of quantitative increases in food intake but of qualitative selection of high-fat, energy-dense foods. It has also been suggested that a genetic predisposition to store rather than oxidize fat may predispose certain individuals to rapid weight gain when they are exposed to a high-fat diet.

Lissner and Heitmann (114) have recently examined prospective data on fat intake and subsequent weight gain and have found that in women, those who exhibited a genetic susceptibility to weight gain showed the greatest tendency to gain weight when exposed to a high-fat diet. In the 1950s Jean Mayer highlighted the need to distinguish between the dynamic period of rapid weight gain and the stable plateau that body weight appears to reach in obesity. The truth is, we are remarkably ignorant of exactly how and at what rate different people gain weight. It appears from laboratory experiments that satiation, PI satiety, and hunger are influenced by food intake in obese subjects in a similar way as in lean people (90). Spitzer and Rodin (5) also note that the majority of studies on eating behavior in normal

weight and overweight individuals conducted between 1969 and 1981 were “impressive in their demonstration of the lack of clear overweight-normal weight differences in eating behaviour.” The situation has not changed much today. They did, however, note that in short-term studies palatability appeared to be the most consistent variable in producing overweight-normal differences in amount of food eaten.

The physiological features and psychological profiles that characterize the obese and may be involved in

the maintenance of the obese state may not necessarily be the same features that led to obesity in the first place (22). Understanding the factors that produce sustained increases in energy intake over expenditure and the time course over which this occurs is crucial for understanding the etiology of obesity. It is also worth mentioning that obesity is a generic category which, like skin color, identifies an obvious recognizable feature of individuals, but explains little of the behavior of those individuals. There are likely to be a number of different factors

**Figure 9** Scheme illustrating the selection and study of phenotypes believed to be resistant and susceptible to diet-induced obesity. At the present time it is important to characterize the differences between these phenotypes at the psychometric, behavioral, physiological, and even genetic levels.

that, individually or together, influence body weight. For instance, it is well known that not all obese subjects are restrained eaters. Similarly, not all obese subjects are insulin resistant. Since it is difficult to categorize which “type” of obesity a person belongs to or indeed how many “types” there are, it is equally difficult to identify the factors bringing about these characteristics. Thus, while there is abundant evidence that certain aspects of diet composition (e.g., dietary fat) are risk factors for weight gain, weight gain on a high-fat diet is not a biological inevitability. It should be remembered that often ~40–50% of the variance in energy intake or subjective appetite in a group of subjects is due to differences between the subjects themselves. This raises the issue of phenotypes (135,136). As regards dietary fat and phenotypes, it is becoming clear that certain high fat consumers (and high energy consumers) do not gain weight while others do so readily. We have recently begun to use these groups of subjects as models for phenotypes resistant or susceptible to diet-induced obesity (DIO). The concept is illustrated in Figure 9. This is no trivial matter. Currently the main practical solution to the current pandemic of obesity is to prevent weight gain in the preobese. How do DIO-resistant and DIO-susceptible phenotypes (the majority of us) differ? What can we understand about the psychometric, behavioral, and physiological profiles of people who are resistant to weight gain on a high-fat diet? Can this knowledge be used to benefit those who are susceptible to weight gain on Western diets?

## VI PALATABILITY AND SENSORY FACTORS

### A Palatability and Food Intake

In considering the capacity for energy intake to rise above energy expenditure, the weakness of inhibitory factors has to be set against the potency of facilitatory processes. The palatability of food is clearly one feature that could exert a positive influence over behavior. The logical status of palatability is that of a construct (it is not objective feature such as protein content or blood glucose) (137,138). Palatability can be influenced by a number of factors including environmental cues and the physiological state of the organism. However, palatability can be operationally defined according to the amount of food consumed, although some authors feel that this is inappropriate for animal studies (26). The independent index of palatability is usually considered to be the subjective appreciation of pleasantness. This subjective sensation

is quantified by expressing it on an objective scale according to standard psychophysical procedures (139). This sensation is usually taken to reflect the hedonic dimension of food. The nature of the relationship among palatability, food consumption, and energy balance has never been systematically determined, although palatability has been invoked as a mediating principle to account for the prolongation of ingestion from a variety of foods due to sensory specific satiety operating in short-term studies.

It may be hypothesized that palatability would exert a powerful effect on intrameal satiety (while food was being consumed), but is there an enduring legacy which influences postingestive satiety? In addition, what is the effect of the expectation of getting pleasure from food on the initiation and maintenance of eating? Although almost everyone would agree that palatability exerts a powerful influence on eating behavior, there is no systematic body of data to explain the strength of the limits of the effect (140).

### B Sweetness, Sucrose, and Sweeteners

For the last decade, there has been a healthy debate about the effects of sweetness, sucrose, and artificial sweeteners (141,142) on EB. The key issue relates to what effects sweetness, plus or minus carbohydrate energy, has on appetite and energy balance. There are three main hypotheses: (i) adding sweetness without calories to foods leads to lower levels of EI than when sweetness with calories are added; (ii) sweetness without calories leads to a cephalic phase stimulation to eat; and (iii) ingestion of sugars (sweetness with calories) correlates with thinness and lowers fat intake, which is itself the reason for the lower body weight. Clearly these hypotheses have enormous implications for appetite and EB control in consumers at large. Sweetness is a factor favoring the selection and subsequent ingestion of sweet foods. Most animals display a preference for sweetness at a very early age, and (until the advent of intense sweeteners) sweetness was a reliable sensory cue that a food was a source of readily available energy in the form of sugars. Conversely, different people exhibit markedly different preferences for sweetness intensities, so simply adding sweetness to foods will not stimulate everyone to eat. Assuming that sweetness does in general stimulate the selection and consumption of these foods, it is pertinent to inquire whether sweetness with or without calories affects appetite and EI.

Despite the common assumption that replacing dietary sugars with intense sweeteners will promote a more

negative energy balance, there is a remarkable paucity of data to demonstrate this effect. There is certainly little epidemiological evidence to suggest that artificial sweetener consumption correlates with lower BMIs, or that increased artificial sweetener consumption in the population has contributed to any reduction in the prevalence of overweight or obesity. According to Mela (143), this effect may be accounted for by the fact that artificial sweeteners tend not to be used so much as a substitute for sugar. Rather, they are *added* to foods to enhance their appeal. The majority of studies that examine the effect of sweetness, sugars, and artificial sweeteners are short-term and therefore do not address the issue of energy balance (144).

Most authors seem to be in agreement that the purely postingestive effects of aspartame do not stimulate intake. Blundell and Rogers initially reported that artificially sweetened drinks can actually stimulate appetite. They suggested that sweetness *per se* provides a sensory cue for carbohydrate calories, which leads to cephalic-phase physiological changes that anticipate energy intake (145). They note that intense sweeteners have only been found to stimulate intake when a food has been sweetened with intense sweeteners or when a less sweet food has been compared with an isoenergetically equivalent food to which sweetness has been added (their “additive principle”) and not when two foods of differing energy density but the same level of sweetness are compared. This they call the “substitutive principle.” Again this area is bedevilled by methodological controversies, such as the appropriate drink vehicle for the sweetener (water or a familiar soft drinks), the time course of the experiment, and the subjects used. Blundell and Rogers (145) argue that the strongest experimental designs contain test of both the additive and substitutive principle. No long-term studies that address energy balance have yet achieved this dual testing.

Black and Anderson (146) report that the use of aspartame-sweetened water leads to an acute short-term increase in subjective appetite in lean men, but that aspartame-sweetened carbonated soft drinks induce a transient suppression of appetite in similar subjects over a similar time frame. The issue is complicated by the fact that satiety can be transiently conditioned by starch-containing drinks that are paired with a given sensory cue such as flavor (147). Once conditioned, similar levels of satiation can be transiently induced by the conditioning stimulus alone. Therefore, the effects of prior conditioning could influence the outcome of short-term studies using vehicles that mimic the sensory properties of similar foods.

In summary, there is little evidence that artificial sweeteners reliably decrease appetite or reduce energy intake, but they could perhaps prevent excess energy intake which would otherwise occur when calories are provided as drinks. There are conditions where artificially sweetened drinks have been found to stimulate appetite and less often energy intake, but there is little evidence to suggest that sweeteners reduce intake. Critically, the fact that intense sweeteners appear to be used as food additives rather than sugar substitutes, suggests that their current use is unlikely to promote a net reduction of energy intake in consumers at large (143). Understanding the applicability of these findings to free-living humans is an important area yet to be resolved. It is also important to bear in mind that a number of experiments examining these issues have used drinks and not solid foods. Mattes (148) has conducted a meta-analysis of feeding responses to either liquid or solid manipulations of the nutrient and energy content of the diet. The analysis suggests that the physical state of ingested CHO intake may be important in influencing subsequent caloric compensation. The reasons for this are unclear but may relate to the rate, timing, and density at which the energy is ingested. There may be a threshold in these parameters, below which energy is poorly detected.

### C Fat and Fat Mimetics

There are a number of low-calorie or acaloric fat mimetics under development. These compounds are poorly absorbed across the gastrointestinal wall and are not metabolized by the calonic microflora. The most extensively studied of these are the olestras, which are a group of compounds that possess a sucrose (rather than glycerol) backbone with more than three fatty acid side chains. To date, 24 studies have examined the impact of olestra-containing foods on aspects of feeding behavior, which are published in 20 reports (see 148 for a review). The general response of human subjects to olestra-based decreases in dietary energy density (ED) is either poor caloric compensation or partial (non-macronutrient-specific) increases in EI. Averaging the degree of energy compensation across 22 studies gives a value of 27% (nonweighted mean). In studies where compensation occurred, fat intake but not energy intake was reduced (149). These effects appear to occur in lean and obese, in men and women, and under a variety of conditions ranging from the laboratory to real life. However, all but two of these studies were short-term. One study suggests that in subjects for whom weight loss is desirable, these deficits

can persist for up to 3 months (150). Subjects with no wish to lose weight may compensate better over longer periods. In another 3-month study, ingestion of olestra-based foods did not induce energy deficits but limited the significant weight gain seen on a full fat control (151). The longer-term effects of olestra on body weight requires further investigation. There is evidence that restrained eaters tend to eat slightly more of olestra-based foods if they know that they are reduced in fat and energy (152,153). This is probably a general response to low-fat foods rather than to olestra *per se*. That olestra-based foods have the potential to provide the sensory qualities of real fat suggests that these foods may be particularly effective in habitual high fat consumers with a sensory preference for dietary fat.

#### D Variety

It has been suggested from a number of short-term studies that have been conducted (154–156), together with the cafeteria-diet model, that sensory variety of foods promotes overconsumption of energy. Furthermore, Le Magnen has shown in rats that simply increasing sensory variety can lead to excess energy intake and weight gain, provided the variety is constantly rotated. Increases and decreases in sensory variety that were stable over time had a much less pronounced effect (33). It has also been hypothesized that this effect may be pronounced in people who are more susceptible to environmental cues (157). We have recently shown that simply increasing the variety of sensorially distinguishable foods of identical nutrient content significantly elevated energy intake in men over 7 days (39). The longer-term effects of sensory factors on appetite and energy have yet to be elucidated. However, the extent to which the food industry invests in and refuses to compromise the sensory attributes of their products bears testimony to the importance of sensory factors in food choice and purchase.

There is therefore a good deal of work to do in considering the relative contribution of sensory versus nutritional determinants of feeding behavior and energy balance. This area of research is of growing importance, since the sensory qualities of the diet no longer necessarily provide reliable information regarding its nutritional content. Some individuals may be more disposed to cues such as palatability or olfactory cues associated with certain foods than to internal (physiological) cues. Disturbed sensory functioning is a major factor involved in the loss of appetite due to pathologies or side effects of the drugs used to treat certain illnesses (6).

#### E Meal Patterns

It has been noted that snacking and commercially available snack food are often believed to elevate EI (158–161). However, there is considerably less evidence that meal or snack patterns contribute to the development of obesity. It is important to note at this point that the relationship between a meal and a snack relates to timing and size of ingestive events in meal-feeding animals. In nonhuman species (and indeed humans) who engaged in numerous small feeding bouts throughout their diurnal cycle, there is little if any distinction between a meal and a snack. Meal-feeding animals are conditioned to ingest the majority of their energy intake in a few large ingestive events in their diurnal cycle, usually at approximately the same time points. Under these conditions, a snack can be defined as an energetically small, intermeal ingestive event (SIMIE). To avoid confusion with a common use of the word to describe a certain type of commercially available food, we use the phrase “commercially available snack foods” to describe those specific foods. Commercially available snack foods tend to differ from the rest of the diet in that they are more energy dense, high in fat and carbohydrate, and low in protein and usually contain a large fraction of their edible mass as dry matter. They are by no means the only food eaten as a SIMIE in many people at large.

There are two alternative hypotheses about how snacking may influence energy intake and body weight: (i) snacking helps “fine-tune” mealtime EIs to match intake with requirements, or (ii) habitual consumption of caloric drinks and snacks between meals is a major factor driving EI up and predisposing people to weight gain and obesity (162).

The evidence in relation to meal patterns, appetite, EI, and body weight is however, indirect and fragmentary. On aggregate, cross-sectional studies tend to support no or a negative relationship between meal frequency and BMI (163–165). However, Bellisle et al. (166) convincingly argue that examinations of the relationship between snacking and energy balance in free-living subjects are extensively flawed by misreporting, misclassification of meal and snacks, and potentially by reverse causality. Under these conditions, it is difficult to draw clear conclusions about the effects of snacking in cross-sectional studies. It is therefore important to conduct controlled laboratory interventions over a number of days in humans.

It is well known in the animal literature that a variety of species can learn to adapt to meal feeding, snacking or totally ad libitum conditions in order to match EI to

requirements (32,33). This suggests some flexibility in adjusting feeding behavior to feeding schedules in order to meet energy requirements. There appears to be very little direct empirical evidence in humans as to whether ingesting snacks *per se* affects appetite and EI. There is some evidence that people who snack frequently exhibit a greater capacity to compensate for changes in the energy content of specific meals, relative to subjects who derive most of their energy intake from fewer, larger meals (167). A recent series of studies by Mazlan have been conducted in which zero, 1.5, and 3.0 MJ of snack foods were consumed as a mandatory intake by human subjects over a week (168). The snacks were similar in taste, texture, appearance, and energy density but not composition. Whybrow has conducted a series of similar studies using commercially available snack foods. Under these conditions where snack foods are consumed as mandatory increments in intake, subjects compensated to some degree, but the net effect was an elevation of energy intake over 7 days. The longer-term effects of such interventions on energy intake and body weight is an area for urgent enquiry.

## VII CONCLUSION

This present chapter aims to represent the current state of research findings in relation to diet and food intake in humans. We hope to point the reader in the direction of some major unresolved and therefore contentious issues that still surround the study of human feeding, rather than construct an uncritical list of major findings in the area. The importance of (frequently ignored) methodological differences in experimental approaches is highlighted, and these are considered in relation to the nature of the appetite system in humans. By considering these together, the strengths and limitations of whole-body human studies of diet and food intake become apparent, as does the importance of supporting these studies with animal models and epidemiological comparisons. Particular emphasis is given to the interactions between physiology and behavior, which characterize human feeding responses. Considerable attention is given to diet composition and feeding behavior, with emphasis being placed on explaining some of the apparent contradictions in the literature and discussing some perhaps premature conclusions that are becoming generally accepted. We discuss the evidence and controversies concerning the influence of dietary macronutrient composition and associated sensory stimuli on (i) quantitative intake, (ii) possible effects on subsequent nutrient selection, (iii) their influence on putative appetite

signalling systems, and (iv) how macronutrient mimetics may influence feeding responses. While a number of issues are becoming resolved (e.g., the role of dietary fat vs. energy density in producing hyperphagia), other important issues emerge—for instance, the role of lean tissue depletion as a signal for post-weight loss hyperphagia and the characterization of phenotypes susceptible and resistant to diet-induced obesity. Greater progress has been made in understanding specific aspects of the appetite system and in identifying its components (through molecular and biochemical studies, often in animal models) than in understanding how these components operate and interact to influence patterns of feeding behavior linked to weight control and weight gain in humans.

The field of appetite and energy balance is becoming increasingly specialized and fragmented. Many researchers concerned with elucidating molecular and genetic mechanism of appetite control have become somewhat divorced from whole body studies of feeding behavior. In some cases, there is less evidence at the whole-body level of the phenomenon being regulated than there is for the mechanisms supposed to regulate it! Thus, the unravelling of the leptin system, believed important in regulating fat mass, proceeds apace. However, clear, direct, empirical evidence that fat mass is actually regulated in humans is embarrassingly scant. It is of critical importance that putative mechanisms of appetite and energy balance control be related to the behavior of the intact organism. Human studies of diet composition and food intake control need to be related to mechanistic work in other species, in order to assess the relevance of these mechanisms to our own species. Feeding studies of our own species in the laboratory need to be related to the general population going about their everyday lives in their natural setting. Given the current emphasis on directing research toward promoting greater human health and well-being, animal and molecular models of compartments of the appetite system provide invaluable information if related to parallel (but less invasive) protocols in human. However, these models need to be made more relevant to appetite and energy balance control in humans.

It is now more important than ever to attempt to integrate the increasingly disparate areas of research specializing in aspects of appetite and energy balance control. We still do not have a synthetic theory of feeding behavior as exists, for example, for biological evolution or quantum physics. A multidisciplinary approach to the construction of integrated models that provide a satisfactory theoretical basis for understanding mechanisms of feeding behavior and inter-

ventions that will successfully manipulate it, is now a clear necessity.

As the food we eat is changed and transformed by food producers and manufacturers for a variety of reasons, understanding the role of the diet in feeding behavior and energy balance is also more important than ever. Structured research strategies that seek to understand the mechanisms underlying quantitative and qualitative feeding behavior, within the context of energy and nutrient balance, may help us keep pace with the rapidly changing nature and effects of the diet that we eat. This knowledge will be vital for the development of successful dietary approaches to weight management, in terms of preventing weight gain in the majority of humans who are susceptible to diet-induced obesity, and developing strategies that lead to sustained weight reduction in the obese.

### I INTRODUCTION

Recent advances in the biology of energy balance have provided a rich cast of molecular players and new pathways underlying the central and peripheral regulation of energy balance. These advances in this dynamic field have invigorated, energized, and added new foci to the obesity research agenda. Several lines of converging evidence have identified the brain integration of central and peripheral neuroendocrine, neuropeptide, and neural signals in the regulation of energy balance as an important research area. This growing area of research activity is the subject of this chapter.

In this chapter, the major peripheral and central neuroendocrine and neural signals in the regulation of energy balance will be identified and discussed. The current understanding of the brain integration of peripheral signals and central neuropeptides in the regulation of energy balance will be discussed. Specific molecules (e.g., leptin, insulin, and NPY) and pathways are then used as examples to illustrate the general principles and overall scheme. The available knowledge about the brain leptin and insulin pathways will be reviewed. This understanding is based on *in vitro* experiments as well as studies conducted in laboratory animals

and humans. This research has revealed that leptin, by acting on diverse brain structures and mechanisms, regulates ingestive behavior, metabolism, and neuroendocrine rhythms, and controls body energy balance. These brain structures and mechanisms form the brain leptin and insulin pathways. The concept of reduced brain sensitivity to leptin in obesity is discussed.

The interaction of leptin with other brain mechanisms is then summarized. When these mechanisms are understood at the molecular level, they should provide new targets for therapeutic interventions that will reduce and maintain body fat at reduced levels and, therefore, increase metabolic fitness, reduce risk factors, and promote improved health of obese individuals (1–3).

The elucidation of the properties, target tissues, pathways, and actions of the circulating hormone leptin (also known as OB protein), which is the product of the *ob* gene, has provided a new pathway and a new context to increase our understanding of the regulation of energy balance. The circulating concentrations of leptin are proportional to adiposity and increase with increasing levels of body fat (4,5). The leptin pathway is one of the long-sought hormonal signal pathways from adipose tissue to the brain that plays a critical role in the regulation of energy balance (1,3,6–8). The brain

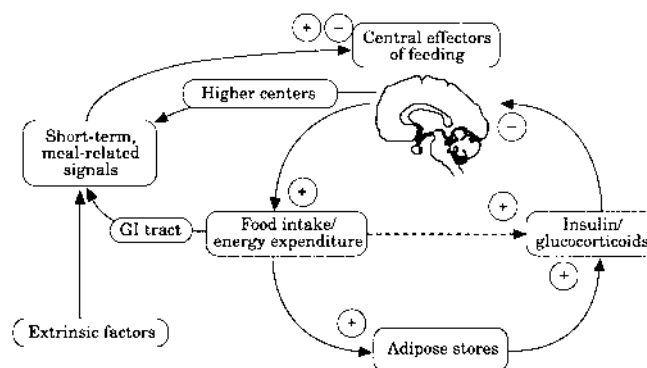

**Figure 1** Schematic model of some of the important elements of the leptin signaling pathway that regulates body energy balance. See text for additional details. (From Ref. 8.)

insulin system is the other peripheral hormonal pathway from adipose tissue to the brain that is critical in the regulation of energy balance (9,10).

Leptin is a polypeptide hormone that is secreted primarily from adipose tissue, circulates in the blood, is bound to a family of binding proteins, enters the brain, binds to its receptors in hypothalamic nuclei and other brain areas, and acts on central neural networks. The *ob* gene is expressed in adipose tissue, bone marrow, and placenta, and leptin is synthesized and secreted

from adipose tissue in proportion to adipocyte volume (11). Several lines of evidence suggest that leptin plays a major role in the control of body fat stores through coordinated regulation of feeding behavior, metabolism, neuroendocrine responses, autonomic nervous system, and body energy balance in rodents, primates, and humans. Leptin expresses these actions through its role in the brain integration of the central and peripheral signals involved in these responses (1,3,7,8). The key elements of the leptin pathway are shown in

**Figure 2** Schematic representation of the brain insulin hypothesis. (From Ref. 9.)

and erroneous integration within the brain. However, results of available studies suggest that these alterations in general, and the brain leptin pathway in particular, play a role in this “resetting response” that is responsible for weight regain following weight loss (1,3,14).

### III REGULATION OF ENERGY BALANCE: BRAIN INTEGRATION OF PERIPHERAL NEUROENDOCRINE SIGNALS

Energy balance is the result of the control of ingestive behavior, metabolism, energy expenditure, and energy storage in adipose tissues (1,3,9,14). While energy intake is a discrete process as individual meals are separated by intermeal intervals, energy expenditure and storage in adipose tissue are continuous physiological processes (15–18). The complex molecular mechanisms by which discrete ingestive behavior, continuous energy expenditure, and dynamic energy storage in adipose tissue are integrated and matched remain largely unknown. The brain insulin system and leptin pathway are two candidate signals for matching intake and expenditure (1,3,9,14). Since the *responsiveness* of both of these systems to insulin and leptin decreases markedly in obesity, appropriate and accurate matching of intake and expenditure will become more unlikely as obesity begins to develop and becomes established.

#### A Control of Food Intake: An Integrated Behavioral Response Dependent on Leptin, Insulin, and Central Neuropeptides

Feeding behavior is the result of the complex central nervous system integration of central and peripheral neural, hormonal, and neurochemical signals relating to brain and metabolic states. Meals are initiated, maintained, and terminated by specific sets of these central and peripheral signals several times a day separated by intermeal intervals without food intake (15–18). These signals include *patterns* of neural afferent traffic; metabolites (glucose); energy flux (fatty acid oxidation, ATP); and hormones (insulin concentrations in plasma and brain, leptin concentrations in plasma, and neuropeptide concentrations in brain) (19,20). The brain structures and mechanisms involved in the detection of these signals and the mapping of them into altered feeding behavior are beginning to emerge. One hypothesis for this integrated neural, metabolic, and hormonal control of food intake postulates the interaction of five classes

of signals: (1) hypothalamic neuropeptides and neurotransmitters; (2) brain insulin; (3) leptin; (4) metabolic signals including transient declines in blood glucose concentrations; and (5) ascending and descending neural inputs (1,17,18,21). These signals interact and provide the central and peripheral integration necessary to regulate food intake and match energy intake to energy expenditure to maintain body energy balance and composition.

Many experimental studies in mice, rats, and many other species demonstrate that several neuropeptides modulate food intake when injected centrally and, in some cases, peripherally (see Chaps. 13 and 14). Among the neuropeptides that have been extensively studied and have major effects on food intake are neuropeptide Y (NPY), cholecystokinin (CCK), corticotropin-releasing hormone (CRH), and enterostatin (9,10). Synaptic concentrations of central neuropeptides and classical monoamine neurotransmitters are thought to be modulated by the central representations of peripheral metabolic state and act on postsynaptic receptors to control energy intake (1,3,9,14,17). Although some investigators still seek the identity of the “one” major neuropeptide controlling human feeding behavior, most of the field has adopted a “parallel” model in which multiple neuropeptides and hormones involved each play a role in determining human feeding behavior (1,3,8,18).

#### B Control of Energy Expenditure

Total daily energy expenditure can be partitioned into resting metabolic rate, dietary and cold-induced thermogenesis, and the energy cost of physical activity ((5–18,22–24) see Chaps. 23 and 24). The energy cost of various kinds of voluntary physical activity (e.g., walking, jogging, swimming) and thermogenesis due to digestion and absorption of food as well as thermogenesis induced by a cold environment have been calculated for both men and women as a function of lean body mass (or “fat-free mass”). Small repeated errors in the “matching” of energy expenditure to energy intake over individual bouts or a series of bouts of physical activity could easily lead to positive energy balance. The effects of exercise on perceptions of hunger are time dependent, complex, and highly variable. Thus, some individuals may experience hunger after exercise, while others may not (25).

The regulation of resting metabolic rate is a complex function of energy intake, energy balance, and hormonal and autonomic neural activity. Resting metabolic rate decreases when an individual reduces caloric intake

and shifts into a state of negative energy balance. This regulatory adaptation appropriately reduces obligatory energy expenditure when energy intake is reduced. Adaptation to reduced caloric intake by reducing metabolic rate requires falling concentrations of both circulating insulin and leptin. However, this same adaptation causes a deceleration of weight loss following voluntary caloric restriction for the purpose of weight loss and contributes to the difficulty of maintaining weight loss, once achieved, over time (22,24).

### C Control of Fat Balance

Just as energy balance is the comparison of total body energy intake and expenditure, a similar balance exists for each macronutrient. The matching of carbohydrate- and protein-derived energy flux and the rates of oxidation and storage are generally well regulated (see Chap. 28). However, fat balance is not closely regulated. Two major problems in the regulation of fat balance predispose individuals to obesity. First, it is known that excess dietary fat does not acutely increase the oxidation of fat for energy. Second, the capacity for fat storage in humans is practically unlimited. Excess calories in the form of fat are readily stored as triglyceride in adipose tissue, with a very high (>96%) efficiency (25).

It is becoming clear that positive energy balance most often results from disruptions in fat balance. However, over the long term, fat balance has to be regulated in order to achieve macronutrient and thus energy balance, and a steady-state body weight. The reestablishment of fat balance following a period of positive energy balance requires a change in the body fat mass. The rate of fat oxidation, which is related to body fat mass, must increase and eventually become equal to the rate of fat intake, and then body fat mass comes into balance and remains in steady state. It is known that fat oxidation varies directly with body fat mass (26), but the mechanisms linking these two parameters are not yet clear. If the dietary fat is increased *without a rapid change in fat oxidation*, this will produce positive fat balance and thus an increase in body fat mass. As body fat increases, fat oxidation will eventually also increase. Body fat mass will then increase to a new level at which fat oxidation matches fat intake, and the body fat stabilizes at this new, higher level (25). Another possibility is that carbohydrate oxidation may not be appropriately inhibited when some individuals are consuming a high fat diet. This would lead to positive energy balance and fat balance.

## IV EXPERIMENTAL MODELS OF OBESITY DUE TO ALTERED LEPTIN PATHWAY

The obese *ob/ob* mice were discovered on the C57BL/6J background in the early 1950s; this mutation results in profound obesity (27). Mice with mutations in the *ob* gene have a premature stop signal and thus fail to synthesize and secrete leptin from their fat cells. These mice have no measurable leptin in their blood and have an early-onset, severe obese phenotype. When treated with small doses of leptin, these mice markedly reduce their food intake, lose weight, and mobilize stored triglyceride. The *db/db* mouse, which arose on the C57BL/KsJ background, is similarly obese and is also characterized by hyperglycemia. When the *ob* gene was transferred to the C57BL/KsJ background, a phenotype almost identical to that of *db/db* mice was observed (28–32). The *db/db* mice have a mutation in the gene coding for leptin receptor, *ob-r* gene, that results in a splice variant in which all the leptin receptors are in the short or nonsignaling form. These mice have high levels of leptin in their blood but are unable to respond to it.

When cross-circulation (or parabiosis) experiments were performed between *ob/ob* and *db/db* mice, the *ob/ob* partner reduced its food intake and lost weight, while the *db/db* partner maintained both its food intake and body weight. In some experiments, the *ob/ob* partner actually died when parabiosed with *db/db* mice. [However, these extreme effects have not been observed in studies with chronic leptin treatment in rodents (8).] These studies led Coleman to conclude that *ob/ob* mice fail to secrete a circulating factor (now known as leptin) from their adipose tissue, although their brain can respond to it and reduce food intake, while *db/db* mice secrete the circulating factor, but their brain cannot respond to it (28,29). Thus, an operational leptin pathway is required for the regulation of lean body composition, and the absence of functional leptin or functional leptin receptors results in obesity. Studies have also demonstrated that the mutated *ob* gene has no effect on the marked hyperglycemia seen when the mutated *ob* gene is on the diabetogenic C57BL/KsJ background; instead, hyperglycemia is thought to be the result of other genes in the KsJ background that render the pancreatic beta cell vulnerable, and eventually to fail to produce adequate amounts of insulin. Low-protein diets have been shown to prevent pancreatic failure in C57BL/KsJ mice with the mutated *ob* or *db* genes. These and other studies demonstrate that mutated *ob* or *db* genes cause obesity, which may or

than in the periphery; that insulin in the brain could potentiate the effects of neuropeptides such as neuropeptide Y (NPY) and CCK; and that circulating steroids interact with the brain insulin in important ways, provided the basis for the paradigm of central/peripheral integration in the regulation of food intake and body energy balance (9).

The brain insulin hypothesis has also provided strong evidence for the involvement of brain neuropeptides, in addition to monoamine neurotransmitters, in the control of food intake. These investigators also demonstrated that central administration of insulin decreased the expression of NPY mRNA in the arcuate nucleus of the hypothalamus. In addition, they also showed that the central administration of insulin increased the expression of corticotropin-releasing hormone (CRH) mRNA in the paraventricular nucleus of the hypothalamus (9,37,73). Thus, central administration of insulin altered the gene expression of two major neuropeptides (decreased NPY and increased CRH mRNAs) that are important regulators of food intake and body energy regulation as well as other biological processes.

## IX INTERACTION AND CENTRAL INTEGRATION OF LEPTIN AND INSULIN WITH OTHER BRAIN HORMONES AND NEUROPEPTIDES

Research on the brain mechanisms involved in leptin action has been stimulated by the long-lasting reductions in food intake and body weight of obese *ob/ob* mice observed following ICV leptin administration (40,41) together with the observation that the circulating leptin concentration was proportional to body fat in humans (4). Central administration of leptin reduced food intake and body weight, altered metabolism, and inhibited NPY-induced feeding of obese *ob/ob* mice, lean mice, and rats.

The neurotransmitters and neuropeptides that directly mediate the actions of leptin have not yet been identified, but experimental evidence is consistent with leptin acting through several brain mechanisms (NPY, AgRP, CART, POMC) to coordinate the regulation of energy balance (74–81) (see Chap. 13). In addition, leptin has been shown to interact with CRH and CRH-dependent neuronal pathways in the regulation of energy balance (63,82). Which if any neurotransmitters and neuropeptides are responsible for the decreased responsiveness to leptin in obesity is not known. However, the neuronal network controlling energy balance

and the descending sympathetic nervous system following peripheral and central administration of leptin is beginning to emerge (81).

Studies of neuronal activity indicate that multiple brain regions contain neurons that are responsive to leptin and are involved in detection of its presence and in generation of its effects. Hyperpolarization of glucose-receptive ATP-sensitive potassium channels and stimulation and inhibition of firing rates have been reported in ventromedial and lateral neurons (83). Direct application of leptin to VMH and LH neurones resulting in both stimulation and inhibition of firing rates have been reported (84). Patterns of activation of brain areas in response to central or peripheral administration of leptin have been measured using c-fos immunoreactivity. Numerous studies have implicated hypothalamic nuclei (arcuate, VMH, DMH, PVN) and other brain areas thought to be involved in the control of energy balance (52,84,85). Brain administration of leptin leads to neuronal activation in many brain areas known to be involved in regulation of food intake and body energy balance including the hypothalamus, perifornic, and cortex. In addition, brown fat was clearly activated in the periphery. This demonstration of leptin activation of the sympathetic nervous system was consistent with norepinephrine turnover studies in brown fat (86) and c-fos studies (63,87,88). In addition, direct recording of efferent sympathetic fibers innervating multiple organs in anesthetized rats demonstrated that intravenous administration of leptin increased sympathetic nerve activity to multiple target organs (89). Colocalization studies using selective antibodies have demonstrated that leptin acts through its receptor on neurons that contain NPY, ACTH, POMC, and melanin-concentrating hormone (MCH) (87). These converging lines of evidence strongly suggest that in addition to several nuclei of the hypothalamus (ventromedial, dorsomedial, paraventricular, and arcuate), other brain areas are involved including perifornic cortex, brainstem, cerebellum, basal ganglia, and cortex (3,14). Thus, the biological actions of leptin to regulate energy balance are the result of a distributed leptin-responsive neural network within the brain.

Recent studies focusing on the arcuate nucleus has provided important insights into the integration of peripheral signals within the brain. Leptin and insulin have been shown to interact on specific receptors on neurons in the arcuate nucleus of the hypothalamus, and the local application of each peripheral signal within the vicinity of the arcuate has profound and predictable effects on food intake and body weight (10,74,77,78,80). Specifically, elevations of either hor-

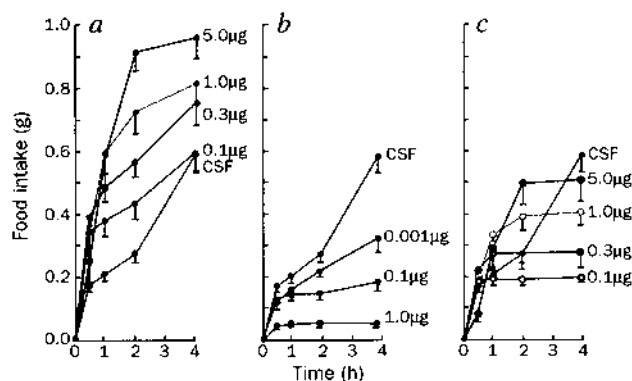

mones in the hypothalamus cause reduced food intake and weight loss, and reductions of the activity of either in the brain cause increased food intake and weight gain. The arcuate contains two groups of neurons sensitive to leptin and insulin. One group synthesizes neuropeptide Y (NPY) and agouti-related protein (AgRP), neurotransmitters that act throughout the hypothalamus to increase food intake and reduce energy expenditure. Both leptin and insulin inhibit the activity of these anabolic NPY/AgRP neurons. The other group of arcuate neurons synthesizes POMC, which is then processed to several small peptides, including desacyl-MSH, which is in turn acetylated at the N-terminus to produce alpha-melanocyte-stimulating hormone (alpha-MSH) and cocaine-amphetamine-related transcript (CART), neurotransmitters that act throughout the hypothalamus to decrease food intake and increase energy expenditures (75,76,79,90–92). Leptin and insulin stimulate activity of these alpha MSH/ CART neurons. The NPY/AgRP and the alpha-MSH/CART neurons influence many of the brain controls over the pituitary, the autonomic nervous system, and the control of food intake (10,74,76). It is very likely that similar neural substrates for the integration of peripheral signals regulating energy balance will be elucidated throughout the brain (10).

### A Example 1: NPY and Leptin

Early in the story of leptin, it was proposed that NPY, a potent stimulator of feeding (49,93,94), was the major mediator of the actions of leptin (41,94,95). This proposal was based on the inhibitory effects of leptin on NPY gene expression (41,46,80,84) and secretion (41) observed in studies of biological activity of leptin. We examined the interaction of brain administration of leptin and NPY on the feeding behavior of *ob/ob* mice to test this hypothesis. We found that leptin inhibited the expected feeding following NPY administration as shown in Figure 4. The magnitude and time course of food intake were determined by the presence of leptin. However, at low doses of leptin, NPY was able to stimulate food intake, indicating a complex interaction exists between leptin and NPY. Similar results have been reported by others (96).

These results suggest that leptin determines the sensitivity (or gain) of the feeding response to exogenous NPY. Leptin, when placed into the lateral ventricle, may alter the binding of exogenous NPY to its receptors. These receptors are critical for feeding or/and may inhibit downstream signal transduction (97). This indicates that leptin can attenuate the actions of exog-

**Figure 4** Effects of ICV administration of leptin on the feeding response to ICV doses of NPY in free-feeding *ob/ob* mice. Cumulative food intake during the 4 hr after the second ICV injection (time=0) is shown. Panels show: (a) increased food intake after doses of NPY alone ( $n=8$ ); (b) decreased food intake after doses of human leptin alone ( $n=7-10$ ); (c) the interaction of 1  $\mu$ g/mouse human leptin and increasing doses of NPY ( $n=5-9$ ). Cumulative food intake following injection of CSF ( $n=25$ ) is shown in each panel for comparison. Food, but not water, was removed from the cage during the 1-hr period between ICV injections. Values represent the mean  $\pm$  SEM. Differences were tested using Student's *t*-test with unpaired samples with  $P < .05$ . (From Ref. 97.)

enous NPY and suggests that the receptor-mediated actions of NPY on feeding can be modulated by leptin (97). Thus, it appears that NPY interacts, particularly in the early postinjection period, with leptin or leptin-dependent signaling processes that contribute to the regulation of body energy balance. However, our results are also consistent with other mediators, besides NPY, of leptin action. This possibility has been strengthened by the report that normal-weight mice lacking NPY respond to peripheral administration of leptin (98). When both the *ob* and *npv* loci are disrupted in mice, the double knockout mice were still obese but the degree of obesity was attenuated by  $\sim 25-40\%$ . These authors conclude that leptin-mediated antagonism of the hypothalamic NPY system is required for normal regulation of body energy balance (99). The mechanism of the functional antagonism of NPY receptors by leptin remains to be determined.

### B Example 2: Circulating Glucocorticoid and Leptin

Strong evidence that NPY and glucocorticoids, acting centrally, play a major role in the development and maintenance of obesity in rodents has been provided

by the work of Bernard Jeanrenaud and colleagues (48,100–105). Chronic intracerebroventricular infusions of NPY or glucocorticoids (dexamethasone) have led to an obesity syndrome: animals with increased body fat, food intake, insulin and leptin concentrations, and elevated triglycerides (103,106). In addition, ICV NPY infusions led to elevated corticosterone (104), while glucocorticoid ICV infusions led to suppressed corticosterone, increased the hypothalamic levels of NPY, decreased those of CRH, and decreased the expression of uncoupling proteins 1 and 3 (106). Adrenalectomy has been shown to completely prevent the obesity syndrome following ICV NPY infusions (101,104). Replacement of corticosterone in these rats restores the ability of ICV NPY to promote the development of obesity (103). When NPY and glucocorticoid are both infused ICV into adrenalectomized rats, an obesity syndrome was observed. Infusion of NPY or glucocorticoid alone failed to reproduce this obesity syndrome (103).

When leptin was administered into the third ventricle of the brain of lean rats, NPY gene expression in the arcuate nucleus was decreased, while corticotrophin-releasing hormone (CRH) gene expression in the paraventricular nucleus was increased in some studies (63). However, other investigators found that leptin decreased CRH gene expression in the PVN (82,92). Since CRH treatment inhibits feeding of rodents when administered ICV (9,37), these results suggest that part of the activity of leptin to inhibit feeding may be mediated through decreased NPY and increased CRH protein levels in specific hypothalamic nuclei critical for the regulation of food intake and body energy balance.

That leptin may interact with the glucocorticoid system is illustrated by (1) the finding that adrenalectomy can restore sensitivity of obese Zucker (*fa/fa*) to centrally administered insulin (9); (2) the well-established effects of glucocorticoids in animal models of obesity (100,101,107), and (3) the actions of leptin on the hypothalamic-pituitary-adrenal axis in fasted mice (108). A series of experiments were conducted in which leptin was administered centrally in adrenalectomized and sham-operated lean rats. A marked increase in potency of the leptin to reduce food intake was observed in adrenalectomized rats (102). When glucocorticoid was replaced using increasing doses, the potency of leptin to reduce food intake was decreased (100–102). Clearly, peripheral corticosterone concentrations can modulate the responsiveness of the brain to leptin. These results provide support for an important interaction between

leptin and the glucocorticoid system in animals and, potentially, in humans.

### C Example 3: Melanocortin and Leptin

Recent genetic and pharmaceutical research has provided strong evidence that the melanocortins and their receptors, particularly MC4-R and MC3-R, play an important role in the regulation of energy balance. In mice lacking MC4-R, late-onset obesity and altered peripheral metabolism have been observed (109). This result, combined with experiments with MC3,4-R agonists (decreased food intake) and antagonists (increased food intake) that are based on alpha-MSH, indicates that the MC4-R participates in a physiological pathway that normally inhibits food intake and fat storage, and may play an important role in late-onset obesity (91). The naturally occurring ligand for MC4-R is unknown, but is widely believed to be alpha-MSH. However, an as yet unidentified protein product of pro-opiomelanocortin (POMC) processing could also be natural ligand. Two other peptides, melanin-concentrating hormone (MCH) (110–112) and agouti-related peptide (AgRP) (92), also act to stimulate feeding.

The evidence for the interaction between leptin and the melanocortin system includes (1) central administration of leptin increases the expression of the POMC gene in the arcuate nucleus (113); (2) a nonselective peptide MC3,4-R antagonist blocked inhibition of food intake by leptin (however, the same antagonist also blocks NPY induced feeding); (3) mice lacking MC4-R responded to ICV leptin by decreasing food intake; (4) when *agouti* ( $A^y/a$ ) mice and *ob/ob* mice were crossed, the combined phenotype appeared to be independent and additive (114); (5) mice lacking MC3 receptor (MC3-R) were also obese (115,116); and (6) when mice lacking MC4-R and MC3-R were crossed, mice with even greater obesity resulted (115), strongly suggesting that the MC4-R and MC3-R are involved in the regulation of energy balance (117). These studies suggest that the melanocortin signaling pathway appears to be downstream of the leptin pathway and that the two pathways converge and may interact at one or more points.

The mouse mutations mahogany (*mg*) and mahoganoid (*md*) are negative modifiers of the Agouti coat color gene, which encodes a paracrine signaling molecule that induces a switch in melanin synthesis. Both *md* and *mg* suppressed the effects of mutation  $A^y$  on both coat color and obesity. These results suggest that *md* and *mg* interfere directly with Agouti signaling,

possibly at the level of protein production or receptor regulation (118).

#### D Example 4: CCK and Insulin and Leptin

The important role of the cholecystokinin (CCK) hypothesis in the study of ingestive behavior is widely acknowledged (119,120). The CCK hypothesis postulated that food in the intestine causes the release of CCK that acts on CCK-A receptors in the vagus nerve to provide sensory information to the brain, which causes meal termination. The critical pieces in that hypothesis were identification of the dependence on the vagus nerve, the identification of a peripheral CCK-A receptor and a receptor in the brain, initially called CCK-B but now known to be the gastrin receptor, and the demonstration that CCK-A antagonists increased food intake (121).

Evidence suggests that insulin may increase the sensitivity of the brain to signals such as CCK (20). That is, when very low amounts of insulin are slowly infused into the brain, doses of CCK that would otherwise have no effect become very effective at reducing meal size (20,122). Similar results have been reported for leptin. Hence, if an individual has lost body weight, the reduced levels of insulin in the brain make the brain less sensitive to CCK. The result is that during meals, more food will be eaten before CCK (and the other satiety signals) elicits satiety, and this will continue until body weight is restored (20).

#### X INTERACTION WITH OTHER NEUROENDOCRINE SYSTEMS

Leptin not only is linked to the regulation of energy balance but also may have a number of additional roles, such as maintaining the normal neuroendocrine activity that is important in the adaptation to starvation and controlling stress responses and functions such as reproduction. Starved mice and leptin-deficient *ob/ob* mice were found to have similar neuroendocrine abnormalities, including an activated hypothalamic-pituitary-adrenal response and depressed thyroid function. In addition, male mice had low levels of testosterone, and female mice had delayed ovulation. When fasted mice were treated with leptin, these neuroendocrine abnormalities were reversed (108,123). Administration of leptin to female *ob/ob* mice restored reproductive function to near normal, and the mice became pregnant and successfully carried litters to term (123). The few

adult cases of human mutations in the *ob-r* genes present with severe obesity and incomplete sexual maturation (124,125).

#### XI ROLE OF THE LEPTIN PATHWAY IN THE BRAIN: A SUBSTRATE FOR INTEGRATION

One possible role for leptin is that of a modulator of gene expression and the resultant synthesis of one or more neurotransmitters and/or neuropeptides within the brain. Much of the research conducted on the leptin pathway has focused on the identification of downstream genes that are regulated by leptin. Five such genes are *npv*, *crh*, *cart*, *agrp*, and *POMC* because leptin has been shown to decrease NPY mRNA and AgRP mRNA levels and increase POMC and CART mRNA in arcuate nucleus and CRH mRNA levels in different areas of the hypothalamus (1–3,7).

Another possible role for leptin is that of a modulator of synaptic transmission within the brain. This could involve alteration of the release or postsynaptic action of one or more neurotransmitters and/or neuropeptides and/or states of one or more presynaptic and/or postsynaptic ion channels. Since recent electrophysiological studies have demonstrated that this hypothesis is correct, then behavioral and metabolic responses to the administration of leptin may be expected to depend on the “background” amounts of these neurotransmitters and/or neuropeptides in synapses or nerve terminals. Since the amounts of these neurotransmitters and neuropeptides change with time, variability in behavioral and/or metabolic responses to administration of leptin would be expected. However, in experiments with sequential administration of leptin and NPY, we were impressed with the very reproducible, rather than variable, nature of these interaction data (97).

Another, alternative role for leptin would be a “coordinator” or “organizer” of the seemingly disparate neurotransmitter and neuropeptide effects on, and responses to, ingestive behavior and body energy balance. The recent demonstration of “coordinated” response of NPY, POMC, CART, and AgRP gene expression to leptin administration (inhibition of NPY and AgRP mRNA, and increased POMC and CART mRNA in arcuate nucleus) provides support for this concept (92). In addition, leptin has been shown to increase CRH mRNA in the paraventricular nucleus in response to central administration of leptin and to interact with CRH-dependent neuronal pathways

(63,82). These responses were “coordinated” in both space (two different anatomical locations) and time (both changes were seen at a common time point that was correlated with the behavioral response) (1–3,7).

These three possible roles do not have to be, and are probably not, mutually exclusive. Indeed, the “coordinator” or “organizer” function of leptin within the brain may emerge from at least two distinct regulatory components mediated by the leptin receptor. One, the action of leptin to regulate gene expression within areas of the brain critical for regulation of energy balance, can be considered responsible for the “long-term” or “chronic” biological effects (e.g., critical molecules which determine the brain responsiveness to leptin, “settling point” for body fat content). Two, the action of leptin to modulate synaptic transmission within the brain by altering the release or postsynaptic action of one or more neurotransmitters and/or neuropeptides

and/or states of one or more presynaptic and/or postsynaptic ion channels can be considered responsible for the “short-term,” “acute,” or “immediate” behavioral (suppression of food intake) and metabolic effects (decreased serum concentrations of insulin and glucose). This “dual-function” mechanism of action, regulation of gene expression and modulation of ongoing cellular function such as neurosecretion, is a common and classical property of hormones. If additional experiments support this dual-function mechanism of action for leptin, it would provide additional evidence for the concept that leptin is a hormone that plays a critical role in the regulation of brain mechanisms involved in the regulation of energy balance.

One representation of this hypothesis at the molecular levels in the hypothalamus is shown in Figure 5. Several “classes” of parallel neural pathways are represented by the five model neurons depicted. Each neuron

**Figure 5** Schematic diagram of hypothetical neural networks controlling energy balance. Several “classes” of parallel neural pathways are represented by the four model neurons depicted. Each neuron is assumed to express the gene, synthesize and release one dominant type of neuropeptide—NPY, CRH, POMC, AgRP (ARP)? Each neuron has the long form of the OB-R receptor (ellipses) and the “final common pathway,” the neuronal network controlling ingestive behavior, metabolism, and energy balance, and has distinct receptors for OB, NPY, CRH, POMC, AgRP and ? Leptin is shown as circles containing OB. Note that leptin can express its biological action through five parallel paths, each mediated by a different neuropeptide—NPY, CRH, POMC, AgRP or ? The ability of leptin to inhibit the actions of released NPY is also shown. (From Ref. 8.)

shown is assumed to have the gene and to synthesize and release one dominant type of neuropeptide—NPY, CRH, POMC, AgRP and ? Each neuron has the long form of the leptin receptor (OB-R) (ellipses), and the “final common pathway,” the neuronal network controlling ingestive behavior, metabolism, and energy balance, has distinct receptors for leptin (OB), NPY, CRH, POMC, AgRP and ? The demonstrated ability of leptin to inhibit responses to NPY is shown by the heavy line blocking the NPY receptor. In this theoretical construct, leptin would fulfill the role of “conductor” integrating the distinct “sections” of the “orchestra” to behave as one while it plays the “symphony.” In this analogy, the “symphony” is the integrated behavioral, neuroendocrine, and metabolic response of an individual; the “orchestra” is the spatially distributed neural network controlling ingestive behavior, metabolism, and energy balance; and the “sections” would be the elements and subsystems of this neural network. This attractive hypothesis has held up since it was proposed in 1995 but must wait further experimental testing in future studies.

## ACKNOWLEDGMENTS

We thank Jack F.R. Curtis for assistance with the conceptualization and execution of some of the artwork. We also thank our many colleagues and collaborators in many laboratories throughout the world for important experiments and stimulating discussions and suggestions. Special thanks to Professor S.C. Woods for pioneering the pathway from the periphery to the brain and back again and sharing his insights.

## Development of White Adipose Tissue

**G rard Ailhaud**

**Hans Hauner**

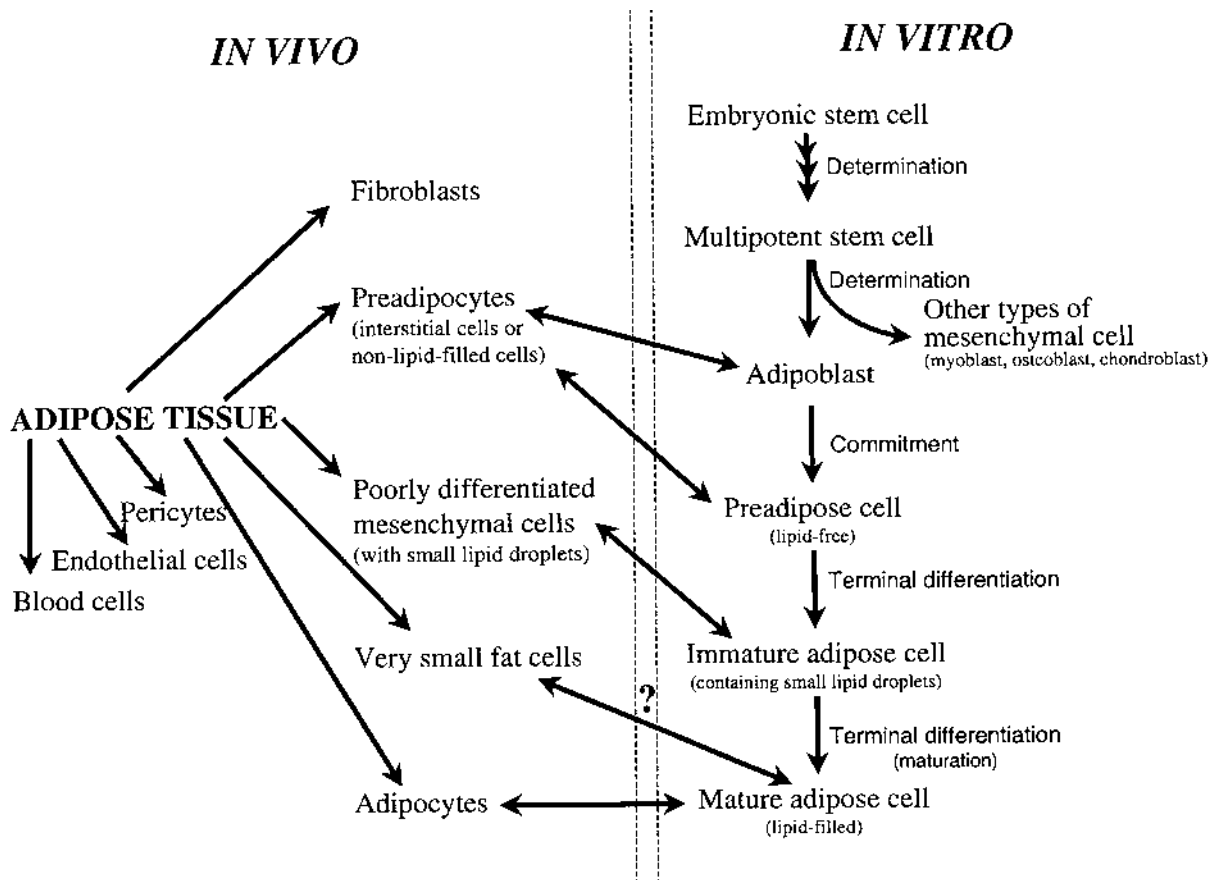

German Diabetes Research Institute, Dusseldorf, Germany

### I INTRODUCTION

The development of white adipose tissue (WAT) represents a dynamic process throughout life. It was long assumed that the acquisition of fat cells was irreversible, but recent observations suggest that apoptosis may also occur in WAT, although to a much smaller extent than in brown adipose tissue (BAT). At the cellular level, there is still limited and partially contradictory information about the characteristics of the cells constituting the adipose tissue organ. This leads in turn to the question of the nature of the factors that regulate the formation of new fat cells from dormant adipose precursor cells or even multipotent mesenchymal stem cells. Once adipose tissue is formed, adipocytes represent between one-third and two-thirds of the total number of cells. The remaining cells are blood cells, endothelial cells, pericytes, adipose precursor cells of varying degree of differentiation, and, most likely, other cell types (1). The existence of very small fat cells in addition to mature adipocytes has also been documented (2). Figure 1 summarizes the various cell types present in this tissue, based on ultrastructural studies in vivo and biological studies in vitro (3).

At present, it cannot be assessed to which extent various morphological descriptions represent only different stages of the cell lineage leading to the characteristic adipocyte phenotype. From a biological

perspective, all different cell types present in the whole body arise from a single fertilized egg. With development, stem cells become increasingly committed to specific lineages. The establishment of embryonic stem (ES) cell lines but also of adult stem cells has opened new experimental approaches (4). The adipose lineage originates from multipotent mesenchymal stem cells that develop into adipoblasts by largely unknown mechanisms. Commitment of adipoblasts gives rise to preadipose cells (usually termed preadipocytes), i.e., cells that have expressed early but not yet late markers and that have not yet accumulated triacylglycerol stores. However, it is becoming more and more likely that multipotent stem cells as well as adipoblasts, which are formed during embryonic development, are still present postnatally. Clearly, in vitro studies with ES cells should provide clues to answer these critical questions and to characterize the key molecular events during adipocyte formation. In vitro, lipid-free, fibroblastlike preadipose cells undergo terminal differentiation into immature adipose cells containing small lipid droplets and then into mature fat cells filled with a few or only one large lipid droplet (Fig. 1). The relationships between brown and white fat during development still remain an open question. The occurrence of brown adipocytes can be detected among all white fat pads, their proportions differ according to the localization of

**Figure 1** Relationships between morphological types in vivo and stages of cell differentiation in vitro. The adipocyte fraction corresponds to adipocytes and very small fat cells. The stromal cell fraction corresponds to a mixture of the other cell types.

the deposit, the ambient temperature, and the species. During postnatal development, the transformation of typical brown fat into white fat can occur rapidly in numerous species and deposits, suggesting a possible transformation of brown into white adipocytes. Conversely, in adult mice as well as in adult dogs, all white deposits can be rapidly and massively converted into brown fat. Using a transgenic approach, it appears that most white adipocytes, if not all, emerge independently of the brown adipocyte lineage during adipose tissue development (5).

## II REGULATION OF ADIPOSE TISSUE MASS IN VIVO

### A Phylogeny and Ontogeny of Adipose Tissue

Among invertebrates, adipose tissue represents an important organ in insects whereas its quantitative importance decreases in arachnids, crustaceans, and

mollusks. Among vertebrates, adipose tissue develops extensively in homeotherms, although its proportion of body weight can vary greatly between species (up to 40% of body weight in cetaceans) or within a species, as is the case in migrating birds and hibernating mammals.

The development of WAT shows wide differences between species. It cannot be detected macroscopically during embryonic life or at birth in most rodents (mouse, rat), whereas it is present at birth in the guinea pig, rabbit, pig, and human. Studies of embryonic development in pigs (6) and humans (7) have emphasized the tight coordination of angiogenesis in time and space with the formation of fat cell clusters.

Histologically, WAT appears well vascularized, many adipocytes being actually in contact with a single capillary. Thus, blood supply is adequate to support the active entry and release of metabolites as well as the secretion of various peptide and nonpeptide factors (8). In the rat, the sole innervation is postganglionic, sympathetic, and noradrenergic. However, sympathetic

innervation of WAT has been reported, albeit less extensively than that of BAT, where sympathetic adrenergic neurons innervate brown adipocytes directly (9).

The characterization of specific growth factors able to trigger and modulate the development of capillaries and fat cell clusters is still in its infancy. Ubiquitous angiogenesis factors have been described, some of which [transforming growth factor- $\beta$  (TGF- $\beta$ ), prostaglandin  $E_2$  (PGE $_2$ ), vascular endothelial growth factor (VEGF), angiopoietin-1] are synthesized and secreted by adipocytes. 1-Butyrylglycerol is solely secreted by adipocytes and appears to act as a potent angiogenesis factor only in this tissue (10). Secreted leptin also appears to act as a highly potent angiogenic factor, consistent with the presence of functional leptin receptors on the surface of endothelial cells (11,12). In addition, endothelial cells as well as fibroblasts and other cells of mesenchymal origin, including preadipocytes and adipocytes, secrete insulinlike growth factor-1 (IGF-1) and IGF-1 binding proteins. This suggests an involvement of IGF-1 in the hyperplastic development of adipose tissue during embryogenesis.

## B Adipose Tissue Development in Early Life

Most studies on the early development of adipose tissue are exclusively based on morphological methods owing the lack of appropriate cell culture models. The "primitive fat organ" of Wassermann develops in the embryo from poorly defined predetermined "Anlagen" long before a visible fat deposition takes place. At this early stage, cells that later will develop into adipocytes are morphologically undistinguishable from other cell types of the connective tissue (13). Only later does fat deposition allow the retrospective identification of these cells as designated preadipocytes. Light microscopy studies in human fetuses suggest that the first traces of a fat organ are detectable between the 14th and 16th weeks of prenatal life. Aggregation of mesenchymal cells in close association with the formation of blood vessels was described as the first indication of adipogenesis in humans.

The first primitive organ structures to be identified at sites where fat accumulates characteristically are fat lobules, long before typical vacuolated fat cells are distinguishable. After the 23rd week of gestation, the number of fat lobules remains constant, while in the subsequent weeks the size of the lobules is continuously growing (14). At the sites of early fat development, a multilocular appearance of adipocytes predominates and probably reflects the early developmental stage

(7). This is interesting, since the morphological development in vitro resembles the developmental steps in vivo. Preadipose cells either from clonal cell lines or from primary cultures usually exhibit a multilocular morphology, not only during early, but also during late stages of in vitro differentiation when the characteristic markers of mature fat cells are fully expressed. The available data do not provide any evidence of significant site- and sex-related differences in early development, supporting the concept that the marked regional differences in adipose tissue distribution in males and females develop later in life, presumably under the control of sex steroids and other hormones. Although some microscopic studies postulate that the second trimester may be a critical period for the development of obesity in later life, the descriptive nature of these data does not allow any firm conclusion in this respect.

At the beginning of the third trimester, adipocytes are found in the principal fat depot areas but are still rather small (7). At birth, body fat accounts for 16% of body weight as assessed by whole-body counting of  $^{40}\text{K}$ . Analysis of biopsy samples of adipose tissue revealed that the increase in body fat during the first year of life from about 0.7 to 2.8 kg is entirely due to an increase in fat cell size, while fat cell number remains unchanged (15). Other studies on this issue gave controversial results, particularly with regard to the development of fat cell number during the first year of life. Such differences may be largely explained by variations in methodology and the general difficulties in assessing total-body fat cell number. In addition, most studies were cross-sectional, which makes interpretation of results more difficult. Longitudinal studies showed a continuous increase in fat cell weight between 1 and 12 months of age (16). It has also been pointed out that in fetal life and early infancy adipose tissue is composed of different cell populations: lipid-containing cells but also many cells that are essentially lipid-free and not readily recognized as adipocytes. Small fat cells in the early stages of fat accumulation may make an important contribution to the adipose cell mass at this age. Therefore, it is tempting to conclude that a gradual accumulation of body fat after birth is mainly reflected by increasing fat cell size (17).

## C Physiology of Adipose Tissue Cellularity in Humans

Apart from species differences, the development of adipose tissue varies according to sex and age. Moreover, the ability of rodents and humans to increase the number of adipocytes also depends on the nature

of the diet and the localization of the adipose depot. The formation of new fat cells following the proliferation of "dedifferentiated" cells during refeeding after a prolonged period of food deprivation, as well as the proliferation of mature adipocytes, still remain controversial events which, if present, should be of low magnitude.

Many studies during the past 25 years have been dealing with changes of adipose tissue cellularity throughout life. Based on such observations, a hypothesis was early established that postulated the existence of sensitive periods in adipose tissue development during childhood. Two peaks for accelerated adipose tissue growth were reported: one after birth, and another be-

**Figure 2** Human adipose precursor cells before and after terminal differentiation. Human adipose precursor cells were maintained in differentiation medium (23) for 12 hr (a), 4 days (b), and 15 days (c). Micrographs were taken with interference contrast. Magnification  $\times 250$ .

tween 9 and 13 years (18). Later studies using different techniques support this hypothesis. When thymidine kinase activity was measured as an index of cellular proliferation, Baum and coworkers found that adipose tissue enzyme activity was highest in infants during the first year after birth. A second, but much smaller, peak in enzyme activity was found in the preadolescent years (19). There is only one study in which cell proliferation and differentiation were measured in cultured stromal cells isolated from adipose tissue samples of children at different ages. Despite some limitations, the results of this study also suggest that the capacity for cell proliferation and differentiation in adipose tissue is highest during the first year of life and less pronounced in the years before puberty (20). Irrespective of the debate on the existence of sensitive periods in adipose tissue growth, Knittle and coworkers demonstrated in a large cohort of children that, starting by the age of 2, children show a small but continuous increase in both cell size and number during childhood over a 4-year observation period (21).

The rate of cell proliferation in adipose tissue slows down during adolescence, and, at weight stability, fat cell number seems to remain fairly constant in adult life. An expansion of adipose tissue mass is believed to be largely due to an enlargement of existing fat cells; only in severe obesity can total fat cell number increase up to threefold (22). However, a recent *in vitro* study showed that adult humans are able to form new adipocytes at any age; even adipose tissue samples obtained from individuals above the age of 60 contain a significant proportion of cells that can undergo differentiation (23). In contrast to established preadipocyte cell lines from rodents, most stromal cells from human adipose tissue seem to be already in a late stage of development. They obviously do not require postconfluent cell division to enter the terminal differentiation program (24). The morphological appearance of the stromal cell fraction isolated from human adipose tissue is rather homogeneous (Fig. 2). The majority of cells exhibit tiny lipid droplets arranged around the nucleus, which can be easily detected by Oil Red O staining or electron microscopy. However, a recent study suggested that these cells are not definitely committed to become adipocytes, but retain a potential to enter other developmental programs under appropriate hormonal stimulation (25).

## D Hormonal Effects on Adipose Tissue Growth

Lessons learned from defined endocrine disorders indicate that hormones can affect both the adipose tissue mass and its distribution pattern. The various hor-

mones reported to be related with dynamic changes of adipose tissue so far are summarized in Table 1. The role of some hormones that may be of particular physiological importance is described next in more detail.

### 1 Macrophage Colony-Stimulating Factor

Macrophage colony-stimulating factor (MCSF) has been implicated in adipocyte hyperplasia. MCSF mRNA and the protein are expressed in human adipocyte and this expression is upregulated in humans gaining weight with overfeeding. Overexpression in rabbits of MCSF by adenoviral-mediated gene transfer increases WAT growth by hyperplasia (26).

### 2 Thyroid Hormones

Hypothyroidism in rats induces a transient hypoplasia, whereas hyperthyroidism results in a transitory hyperplasia of retroperitoneal and epididymal fat tissues (27), which is in favor of an accelerating effect of tri-iodothyronine ( $T_3$ ) on the precocious formation of mature fat cells. Interestingly, in hypophysectomized pig fetuses, but not in intact fetuses, thyroxine ( $T_4$ ) profoundly enhances adipose tissue development by hyperplasia and hypertrophy, which points to a role of  $T_4$  as an adipogenic agent, at least in early developmental stages, and suggests that growth hormone (GH) antagonizes the adipogenic potential of thyroid hormones (28).

**Table 1** Effect of Selected Hormones, Cytokines, and Growth Factors on Adipose Tissue Cellularity from *In Vivo* and *In Vitro* Studies

| Factor            | Fat cell size | Fat cell number   | Fat mass |
|-------------------|---------------|-------------------|----------|
| Insulin           |               |                   |          |

### 3 Insulin

Insulin is an anabolic hormone that potently supports lipid storage in adipose tissue, but is also a powerful growth-promoting factor. Insulin favors lipid accumulation not only via stimulation of glucose uptake and increased lipoprotein lipase (LPL) activity but also by inhibition of catecholamine-induced lipolysis. The lipogenic effect of insulin is already evident in fetal life, since hyperinsulinemia in the fetal circulation of mothers with gestational diabetes frequently results in macrosomia with an increase in fat mass. In streptozotocin-diabetic rats, insulin stimulates the *in vivo* cell proliferation in white adipose tissue. This growth-stimulating effect was observed in interstitial cells rather than in other cell types, including lipid-containing cells (29). In cell culture experiments, insulin was found to be both an adipogenic hormone in 3T3-L1 fibroblasts (30,31) and a positive modulator of adipose differentiation in clonal Ob17 preadipocytes (32) as well as in rat and human adipocyte precursor cells in primary culture (23,33). The growth-promoting effect of supraphysiological insulin concentrations may be exerted via the IGF-1 receptor. An interesting phenomenon in this context is insulin-induced lipohypertrophy in diabetic subjects. This clinical observation is frequently made when insulin is repeatedly injected at the same subcutaneous site, particularly in young women. Analysis of adipose tissue cellularity revealed that the mean fat cell size is only moderately increased in lipohypertrophic areas as compared to unaffected sites, strongly suggesting that, in addition, adipocyte precursor cells are recruited (Hauner and coworkers, unpublished observations).

### 4 Growth Hormone

Growth hormone (GH) deficiency is known to be associated with an increased body fat mass. Children with GH deficiency have enlarged fat cells but a reduced number compared to healthy children (34). Treatment with GH normalizes these disturbances of adipose tissue cellularity (34,35). The increased body fat mass in GH-deficient subjects is mainly localized in the abdominal region, and administration of GH results in preferential reduction of fat cell size in the abdomen (35). Studies using computerized tomography (CT) suggest that the visceral depots are particularly sensitive to the effect of GH. A 6-month treatment with recombinant GH of patients with adult-onset GH deficiency resulted in a 4.7-kg reduction of adipose tissue mass. Subcutaneous adipose tissue decreased by an average of 13%, whereas visceral adipose tissue was reduced by 30% (36). In contrast, in patients with

acromegaly, a reduced fat mass was observed that returned to normal after treatment of the hormone excess by octreotide or pituitary surgery.

The mechanisms of the slimming effects of GH are only partially understood. Chronic administration of GH to GH-deficient children was found to induce a significant reduction in basal lipogenesis and a decreased antilipolytic action of insulin leading to a significant reduction of adipocyte size, but only in the abdominal depot (35). In cultured human adipose tissue pieces, GH counteracted the stimulatory effects of glucocorticoids on LPL activity without affecting LPL mRNA levels (37). On the other hand, recent data suggest that GH has an intrinsic lipolytic activity, which can be demonstrated in fat cells from GH-deficient adults and is even enhanced after long-term GH administration (38). As many biological actions of GH are mediated via the induction of IGF-1 synthesis, attention has been paid to the question of whether the metabolic effects of GH on adipose tissue are exerted by IGF-1. Studies in porcine preadipocyte cultures have shown that GH is able to increase IGF-1 mRNA at least twofold. Since the increase in local IGF-1 production was associated with a decrease in adipocyte development, the authors concluded that local IGF-1 may contribute to the suppression of the adipocyte phenotype (39). In contrast, IGF-1 increased adipose conversion in rabbit adipocyte precursors. The stromal-vascular cells from the perirenal adipose tissue were found to secrete large amounts of IGF-1 and IGF-binding proteins (40). In cultured human preadipocytes, GH was found to considerably reduce adipose cell differentiation. Upon stimulation by GH, stromal cells responded with an increased synthesis and release of IGF-1, which was followed by increased DNA synthesis as assessed by tritiated thymidine incorporation. It was also demonstrated in this study that human adipose cells have specific GH receptors and that the hormone exerts a variety of direct metabolic effects such as inhibition of glucose uptake and stimulation of lipolysis, which may cause a net loss of stored lipids (41).

### 5 Glucocorticoids

Clinical observations suggest that patients suffering from glucocorticoid excess develop an increased adipose tissue mass with a characteristic preferential accumulation of fat in the trunk and neck region. In a recent study using CT, surgical treatment of women with Cushing's disease was associated with a significant reduction of all adipose tissue depots except for leg

adipose tissue. However, visceral, head, and neck adipose tissue depots were more markedly reduced than other depots (42). Studies of adipose tissue cellularity in Cushing's syndrome have shown that this expansion is primarily due to enlarged abdominal fat cells (43). This effect can be at least partly explained by the finding that fat cells from the abdominal depot exhibit more cytoplasmatic glucocorticoid receptors and higher receptor mRNA compared with adipocytes from other regions (44). In Cushing's syndrome, fat cell hypertrophy in the abdomen appears to be due to elevated adipocyte LPL activity and also to low lipolytic activity (43). Moreover, glucocorticoids are known to be potent promoters of the adipose differentiation process, a mechanism that may also contribute to adipose tissue expansion during glucocorticoid excess (23).

The role of glucocorticoids and the importance of the hypothalamic-pituitary-adrenal axis in the excessive development of adipose tissue have been documented in two models of transgenic mice. In one model (45), a reduction of the glucocorticoid receptor in the brain and also in liver and kidneys was obtained with an antisense mRNA, whereas in a second model (46) overexpression of corticotropin-releasing factor (CRF) was achieved. In both cases, the observed increase in corticotropin and corticosterone levels was accompanied by an increase in adipose tissue mass, with the development of Cushing's syndrome in CRF-overexpressing mice.

## 6 Sex Steroids

The role of sex steroids in the hyperplastic development of adipose tissue has not been well documented. Direct effects of sex steroids have been postulated for decades, but information on their molecular receptors in adipocytes of animals and humans remains scanty. Androgen receptors and estrogen receptors (ER) have been originally characterized in rat adipose tissue (47,48). It was recently demonstrated that both estrogen receptor subtypes are detectable in human adipocytes in a striking depot-specific distribution. The ER- $\beta$  is markedly reduced in intra-abdominal adipose tissue as compared to subcutaneous adipose tissue, and the visceral adipose tissue of men contains less ER of both subtypes than the visceral fat obtained from women (49). There is some evidence for the expression of progesterone receptors by adipose cells (50), but subsequent studies found only very low levels. As adipocyte precursor cells are well known to be an important site of estrogen production, particularly after menopause, a paracrine effect of estrogens on adipocytes is rather likely.

Studies by magnetic resonance imaging (MRI) indicate that puberty in girls is associated with the preferential accumulation of adipose tissue in the gluteal and femoral region (51), suggesting that the divergence of sex steroid metabolism and serum levels among boys and girls may be responsible for the development of sex-specific fat distribution patterns at this age (52). In women, decreased ovarian estrogen production during menopause and the subsequent change in the balance between estrogens and androgens may cause a shift in fat distribution toward more abdominal pattern. Estrogen replacement therapy appears to result in a reduced amount of trunk adipose tissue as determined by dual-energy x-ray absorptiometry (53).

In men, low testosterone levels are associated with enlarged visceral adipose tissue depots (54). When middle-aged, abdominally obese men are treated with testosterone, a small decrease in visceral fat mass in conjunction with an improvement of insulin resistance and associated metabolic disturbances is observed (55). A possible explanation for this observation is that androgens are positive effectors of lipolysis in concert with GH, thereby decreasing the size of the abdominal fat cells, but may not be directly involved in the regulation of fat cell formation (54). Another interesting finding is that alcoholic men have more adipose tissue localized in the intra- and retroperitoneal depots than abstinent men, also possibly due to a lower androgen activity (56).

## 7 Nutrients

Long-chain fatty acids (FAs) have been shown to trigger *in vitro* differentiation of preadipose into adipose cells (57). *In vivo*, the effects of increased FA uptake on adipose tissue development have been remarkably illustrated in transgenic mice overexpressing human LPL in skeletal and cardiac muscle. Increased FA entry in both tissues is associated with weight loss due to some loss of muscle mass and, quite strikingly, to the virtually complete disappearance of adipose tissue (58). *In vivo* also, the nature of FA present in triacylglycerol molecules is of importance in adipose tissue development as feeding rats a diet rich in saturated fat leads to a threefold increase in the number of adipocytes in the retroperitoneal depot compared to the number of adipocytes in animals fed a diet rich in polyunsaturated fat, which indicates that saturated FAs are more potent than unsaturated FAs in promoting mitotic clonal expansion and/or terminal differentiation of preadipose cells (59). In a recent study, Cleary and coworkers investigated the effects of diets containing either

coconut oil (rich in saturated fatty acids) or safflower oil (rich in mono- and polyunsaturated fatty acids) on adipose tissue cellularity in various fat depots in Zucker rats. It turned out that feeding unsaturated fatty acids favored fat cell hyperplasia, probably through enhanced recruitment of adipocyte precursor cells, whereas saturated fatty acids preferentially promoted hypertrophy through enhanced triacylglycerol accumulation of existing adipocytes (60).

In addition to hormones, normal glucose homeostasis appears to be essential for adipose tissue development. Transgenic mice overexpressing the glucose transporter GLUT4 selectively in adipose tissue have enhanced glucose disposal *in vivo* and develop increased adiposity due to adipocyte hyperplasia (61). In contrast, mice deficient in GLUT4 exhibit growth retardation accompanied by a severe reduction in adipose depots despite a nearly normal glycemia (62).

## E Lipectomy

Surgical removal of adipose tissue and careful observation of its regeneration is another appropriate approach to study the regulation of adipose tissue growth and body weight *in vivo*. To date, many studies have been performed to investigate the effect of lipectomy on adipose tissue regeneration in a variety of species and depots and under various conditions. However, the results of these studies were inconclusive, since the response to lipectomy was found to depend on various factors such as species, region of excision, time after operation, extent of removal, and type of diet. Nevertheless, in most animal studies a clear tendency for regeneration of the lost tissue was apparent at least in the perirenal and subcutaneous fat depots, but restoration at the site of excision was not always complete. In both rat and rabbit, the regenerative response was highest in the perirenal fat depot (63,64). In contrast, surgical removal of the epididymal fat pads did not lead to regeneration. These data are to some extent compatible with *in vitro* findings indicating that adipocyte precursor cells from the perirenal region have a higher capacity for proliferation and differentiation than stromal cells from other depots (33,65). Morphological studies in rats showed that adipose tissue regeneration at the inguinal site occurred in close association with revascularization and blood supply. Immediately after lipectomy, thymidine kinase activities are elevated at the sites of removal, but subsequently slowly drop to a level that is still above normal. Both total fat cell number and average fat cell size continuously increase during this process. Thus, the regeneration of adipose tissue resem-

bles the processes that occur in developing adipose tissue and involves the new formation of fat cells from preadipocytes (66).

Two other aspects are of potential importance. One is related to the question whether adipose tissue regrowth after lipectomy can also occur at other sites, thereby replacing the lost tissue mass. Faust and coworkers reported a compensatory fat deposition in nonexcised tissues after removal of epididymal and inguinal fat pads in rats (63). In a recent study, lipectomy of >50% of subcutaneous adipose tissue in adult female Syrian hamsters led to similar levels of body weight after 3 months on a high-fat diet. However, there was no visible regrowth of subcutaneous adipose tissue, but an increase in the intra-abdominal fat together with higher insulin and triglyceride concentrations than in sham-operated animals. The authors concluded from the data that subcutaneous adipose tissue acts as a metabolic sink that protects against visceral obesity and its metabolic disturbances (67). In another study, in moderately obese rats, surgical removal of visceral fat resulted in improvement of hepatic insulin resistance and, interestingly, a marked decrease in gene expression of both tumor necrosis factor- $\alpha$  (TNF $\alpha$ ) and leptin in subcutaneous adipose tissue (68). If these latter observations hold true in humans, surgical removal of significant amounts of subcutaneous adipose tissue could cause a redistribution of lipid stores to visceral sites, thereby favoring undesirable metabolic effects, whereas reduction of the visceral fat mass may result in an amelioration of insulin resistance and its associated metabolic disturbances.

It is largely unknown whether the site-specific differences in regenerative capacity are due to inherent characteristics of the local tissue or to differences in the local environment. Circumstantial observations in humans are apparently in favor of the former possibility; skin transplantation from the abdomen to the forearm or to the back of the hand can lead to local hypertrophy of the transplant in case of body weight gain. The cellular composition of the subcutis may vary substantially depending on the anatomical location, and some particular skin areas may lack preadipose cells, which normally excludes the development of fat cells. Systematic studies on adipose tissue regrowth are missing in humans despite the widespread application of suction lipectomy and dermolipectomy for cosmetic reasons, particularly in women. Much work needs to be done to ascertain to which degree and under which conditions adipose tissue regrowth can occur in humans.

## F Regional Differences in Adipose Tissue Growth

Many studies in animals and humans indicate that various aspects of adipocyte growth and function depend on the anatomical origin of the cells (52,69). The available methodology may not always allow an accurate assessment of differences, particularly if they are only modest. Regional differences may concern not only the metabolism of adipocytes but also the capacity to form new adipocytes.

Most cell culture studies on possible regional differences in adipose tissue growth were performed in rodents. In rats, it has been repeatedly demonstrated that perirenal preadipocyte cells replicate more extensively under cell culture conditions than epididymal cells (65). In addition, perirenal cells differentiated more readily by morphological and biochemical criteria (33,65). In vitro differentiation of epididymal preadipocytes was also less pronounced than that of inguinal subcutaneous preadipocytes (70). These results are in good agreement with those obtained in adipose tissue cellularity studies. Available data also suggest that the composition of the preadipocyte precursor pool differs from region to region (65,71). Djian and coworkers reported that the adipocyte precursor populations derived from rat perirenal and epididymal fat are composed of cell clones that vary in capacity for replication and differentiation. Since these differences between rat perirenal and epididymal depots were still detectable during secondary culture, the authors speculated that this variation among fat depots may have an intrinsic basis (65).

It was hypothesized that regional differences in adipose tissue growth may result from variations in the distribution of hormone receptors, but there is also growing evidence that regional differences are due to differences in the local environment of the cells. Innervation and blood flow are two major determinants of the local milieu. Comparative studies have noticed that mesenteric fat cells receive more blood than subcutaneous cells (8,72). In accordance with this finding, the stromal-vascular cell fraction of omental adipose tissue contains a high proportion of endothelial cells, while the same fraction obtained from subcutaneous adipose tissue is almost free of endothelial cells. It is obvious that a better blood supply may provide greater levels of humoral factors that are involved in the regulation of adipose tissue growth and also more substrates for lipid accumulation or removal. In an elegant approach, Cousin and coworkers have recently demonstrated that a local sympathetic denervation of white adipose tissue

in rats induces preadipocyte proliferation without affecting metabolic function. The surgical denervation also resulted in an accelerated recruitment of precursors as assessed by increased expression of an early marker of differentiation (73).

Only sparse data are available on site-specific differences in adipose tissue cellularity and growth in humans. They indicate that intra-abdominal fat cells are smaller than subcutaneous cells, while published results on variations in fat cell size among subcutaneous depots are inconclusive or found to be influenced by many factors, such as age, hormonal status, and diet. A comparison of adipose tissue cellularity between young and middle-aged women revealed that the latter have more body fat than the former. This difference was exclusively explained by larger fat cells in all depots, while the younger women had a significantly higher total fat cell number. The age-related increase in fat cell size was particularly pronounced in the abdominal depot. The authors conclude that abdominal fat cells are more sensitive to nutritional and/or hormonal factors than those from other regions (74).

Very limited information is available on regional differences of adipose tissue development in humans. Pettersson and coworkers compared the capacity for adipose differentiation in stromal cells from omental and subcutaneous adipose tissue. They reported that more omental than subcutaneous cells were converted into adipocytes in an enriched viscous suspension medium (75). However, in this system high serum concentrations were used, which are now known to strongly inhibit adipose differentiation in human cells due to a high mitogenic and antiadipogenic activity. In two recent studies, the relative capacities of stromal cells from subcutaneous and omental adipose tissue to undergo adipose differentiation were studied using serum-free culture conditions in the presence of thiazolidinediones, a new class of antidiabetic agents known to activate the nuclear transcription factor of peroxisome proliferator-activated receptor- $\gamma$  (PPAR $\gamma$ ). In the study by Adams and coworkers, only stromal cells from subcutaneous fat were able to develop into adipocytes upon exposure to thiazolidinediones, although PPAR $\gamma$  was expressed at similar levels in both depots (76). In contrast, Van Harmelen and coworkers were unable to find a depot difference in response to thiazolidinediones between stromal cells from the two adipose tissue depots (77). This discrepancy may be partly due to differences in the methods applied as well as in the populations studied, but further investigations are required to clarify this issue. In another study, the capacity for adipose differentiation was compared in

cultured stromal cells from the abdominal and femoral adipose tissue obtained from obese women by needle biopsy. Under serum-free, hormone-supplemented culture conditions, glycerol-3-phosphate dehydrogenase (GPDH) activities used as an index of adipose differentiation were significantly higher in the cells from the abdominal region, while other parameters such as number of stromal cells per gram adipose tissue were not significantly different (78).

### III DEVELOPMENTAL ISSUES IN THE LEAN AND OBESE STATE

#### A Adipose Tissue Cellularity

An excessive amount of body fat can result from enlarged fat cells or an increase in fat cell number or both. In humans, the study of Salans and coworkers emphasized that childhood-onset obesity is characterized by a combination of fat cell hyperplasia and hypertrophy, in contrast to adulthood-onset obesity where fat cell hypertrophy is predominant (18). Indeed, studies in lean and obese children suggest that obese children exhibit more rapid and earlier elevations in both fat cell number and cell size during childhood and adolescence (21). In contrast, studies in adults indicated that obese subjects have larger adipose cells than lean subjects but no significant increase in fat cell number (18). However, further studies revealed that development of hyperplasia can also occur in adult life. During excessive weight gain, as seen in severely obese adults, both fat cell size and fat cell number increase independent of the time of onset of obesity (22). It was concluded from such studies in humans and rodents that an increase in the number of mature fat cells did not occur until existing cells reach a critical cell size (22,79). Since fat cell size is varying in different adipose tissue depots, it was speculated that this phenomenon is regulated at the local level (16,79). In addition, there is now convincing evidence that new adipocytes can be recruited throughout the whole lifetime (23).

The few studies comparing adipose tissue growth in lean and obese humans do not allow any firm conclusions concerning the main characteristics of fat cell proliferation and differentiation. Pettersson and coworkers reported that the replication rates of stromal-vascular cells isolated from adipose tissue of lean and obese subjects were similar. In addition, no difference in the capacity for differentiation was observed between cells from nonobese and obese individuals regardless of tissue site, arguing against a genetic predisposition at

the cellular level (75). On the other hand, Roncari and coworkers reported an exaggerated replication and differentiation of cultured adipocyte precursor cells from massively obese subjects as compared to lean controls, which may indicate that in this particular subgroup an intrinsic defect could be responsible for fat cell hyperplasia and facilitate the development of massive obesity in humans (80). Up to now, these data await confirmation from other groups.

Apart from these limited data in humans, many *in vitro* studies have been performed in animal models of obesity to determine if there are significant differences in the capacities and mechanisms to form new adipocytes between obese and lean animals and, in particular, to look for intrinsic differences in genetic models of obesity. Most studies have been carried out in Zucker rats. Compared with lean rats, a decreased as well as an increased adipogenic capacity of preadipocytes derived from obese Zucker rats has been reported. However, under strictly controlled serum-free culture conditions, the only difference between lean and obese animals was that adipose conversion in cells from older obese rats was lower than from lean controls (81). It may be speculated that, owing to higher adipogenic activity, preadipose cells in advanced stages of development are recruited more extensively and rapidly in obese than in lean animals. Thus, the conclusion could be that obesity and its metabolic consequences induced by the *fa* gene cause secondary changes in the cellular composition of the stromal cell fraction. Other studies on this issue did not describe consistent differences in the capacity for preadipocyte proliferation and differentiation between obese and lean animals, arguing against an intrinsic basis for the above-mentioned differences in adipose tissue cellularity.

#### B Modulation of Adipose Tissue Cellularity by Diet and Weight Change

The relationship between nutrition and adipose tissue cellularity is crucial for the understanding of adipose tissue expansion. There is evidence from many studies that early nutrition can affect fat cell number in adult life. Fetal overnutrition as seen in gestational diabetes leads to larger birth weight and to subsequent obesity in childhood and later life, whereas data are inconsistent as to whether undernutrition during fetal growth is a risk factor for increased body weight later in life (82). To date, there is no information on whether early human nutrition affect fat cell development and cellularity.

In adult rats, feeding a high-fat diet can increase fat cell number (79), while energy restriction is only asso-

ciated with a decrease in fat cell size but not in number, indicating that dietary manipulation in adulthood cannot reduce fat cell number. This has been elaborated in experiments where rats were overnourished for a long period of time, which resulted in an increase in both fat cell size and number. Discontinuation of the experimental diet was followed by a decline in average fat cell size until it reached the level of normal control rats. However, fat cell number remained at the high level achieved during overfeeding.

It is also uncertain whether extreme dietary restrictions can affect fat cell number. In a study of severe long-term food deprivation causing up to 99% reduction in white adipose tissue mass, there was no evidence that fat cells were lost. After refeeding, no change in fat cell number was observed despite marked changes in endothelial and nonadipocyte mesenchymal cell number adipose tissue (83). These data are not consistent with the results of some older studies that showed a decrease in fat cell number after long-term weight reduction (84). In a more recent study, induction of diabetes in rats by streptozotocin resulted not only in a marked reduction in fat cell size, but also in a decrease in white adipose tissue cellularity as assessed by quantitative cellular analysis. Interestingly, the tiny adipocytes were characterized by the presence of multilocular triglyceride droplets (85). It would also be interesting to know whether fat cell hyperplasia found in the obese state can decline during prolonged maintenance of reduced weight. Again, in most studies, the number of fat cells was not normalized in either form of obesity even after extended periods of weight reduction. Obviously, an established fat cell hyperplasia cannot be reversed by extreme nutritional intervention including extreme starvation (83,84). However, one has to keep in mind that some of the contradictory findings can be due to limitations of the applied methods. For various reasons, the classical methodological approaches for the determination of adipose tissue cellularity are inaccurate and do not allow a reliable identification of the cell populations present in adipose tissue. This makes it extremely difficult to distinguish early preadipocytes as well as tiny fat cells from other cell types in adipose tissue.

In humans, short-term studies have demonstrated that moderate weight changes are associated only with changes in fat cell weight but not in fat cell number (86,87). To date, there is only one study that investigated the long-term effects of weight change on adipose tissue cellularity. The authors reported that prolonged reduction in body weight in adult women over 6–9 years reduced the number of monolocular adipocytes (16).

Other evidence for a possible reduction of fat cell number by weight loss comes from a study of morbidly obese subjects undergoing gastric surgery. After a mean weight loss of 30–40 kg, fat cell size was markedly decreased in all adipose tissue depots. In addition, the calculated fat cell number was significantly reduced (88). Irrespective of methodological limitations, these reports raise the possibility that at least some adipocytes can completely lose their lipids and regain a state of lipid depletion. This remains an important issue, since it was repeatedly hypothesized that persistence of hypercellularity may contribute to the difficulties encountered by postobese subjects to maintain a reduced body weight.

Adipose tissue growth seems to depend not only on total caloric intake but also on the composition of the diet. Older animal studies suggested that dietary fat can induce hyperplastic adipose tissue growth independent of body weight gain (89,90). This effect was also observed when strictly isocaloric diets were fed (91). This close relationship between fat intake and adipose tissue growth may be substantiated by recent *in vitro* data demonstrating that exogenous triglycerides via fatty acids released after hydrolysis can promote adipose differentiation. These new findings may provide a better insight at the cellular level as to why a fat-rich diet favors adipose tissue expansion in humans (57).

### C Apoptosis and Dedifferentiation of White Adipose Cells

There is now abundant information on the role of cell proliferation and differentiation to determine adipose cellularity. In contrast, little is known about possible mechanisms to decrease fat cell number. Only recently evidence is emerging that white adipose cells can undergo apoptosis or programmed cell death. It was recently reported that *in vitro* apoptosis is enhanced by growth factor deprivation (92) and TNF $\alpha$  (93). Particularly, in the presence of TNF $\alpha$ , apoptotic cells were seen in cultures of both human preadipocytes and adipocytes at rates between 5% and 25% (93). This effect of TNF $\alpha$  may be partly mediated by an increased adipose expression of the proapoptotic interleukin-1 $\beta$  (IL-1 $\beta$ ), as recently observed in human preadipocytes and adipocytes. In the same study, TNF $\alpha$ -induced apoptosis was inhibited by glucocorticoids (94).

Insulin also appears to be involved in the regulation of fat cell apoptosis. Depletion of insulin in mice led to adipose-specific cell death in obese but not in lean animals (95). Feeding a diet supplemented with con-

jugated linoleic acid (CLA) to mice resulted in a reduction of body fat due to apoptosis. Under these conditions, TNF $\alpha$  and UCP-2 expression were 12- and sixfold upregulated in adipocytes from CLA-fed mice compared to fat cells from control mice. With decreasing body fat the mice developed lipodystrophy associated with hepatomegaly and insulin resistance (96).

In humans, it has been demonstrated that patients with some malignancies exhibit signs of adipocyte apoptosis *in vivo* (97). This and another report (98) showed that apoptosis is higher in omental than in subcutaneous adipose cells indicating that regional fat distribution may be partly regulated by differences in apoptosis. The *in vitro* data currently available suggest that apoptosis is mainly found in human preadipocytes. During *in vitro* differentiation, preadipocytes appear to acquire a relative resistance to apoptosis due to an increasing synthesis of the cell survival proteins Bcl-2 and neuronal apoptosis inhibitory protein (99).

Other studies suggest that mature fat cells can be induced to reverse the adipocyte phenotype under certain circumstances. TNF $\alpha$  was found to cause a dedifferentiation of cultured human fat cells after long-term exposure leading to a complete loss of stored lipids without a change in total cell number (100). It was recently reported that adenovirus-induced hyperleptinemia in normal rats results in rapid body fat loss. The elevated leptin concentrations not only depleted adipocyte lipids but transformed the adipocytes into cells that oxidize lipids, lose characteristic adipocyte markers, and express preadipocyte markers (101).

Although the existence of apoptosis and dedifferentiation in white adipose tissue is now established the physiological importance of these phenomena is still unknown. It is also unclear whether apoptosis is involved in the pathophysiology of obesity and, if so, to what extent and by what mechanisms. The question may also arise whether this new insight can be used to develop new therapeutic strategies.

#### IV STUDIES OF ADIPOSE TISSUE DEVELOPMENT IN VITRO

##### A Cellular Models for the Study of Adipogenesis and Adipose Cell Plasticity

Cell culture techniques have the advantage that the effects of single factors can be studied under strictly defined conditions. This methodology is an ideal tool to unravel mechanisms of hormone action or cell development. However, *in vivo*, the physiological function of a

specific cell type or organ strongly depends on its communication with the environment. As part of a complex, highly integrated organism, the adipose tissue depots are interacting with surrounding and also with distant tissues. To fully understand and corroborate the physiological importance of *in vitro* findings in any tissue it is essential to perform additional *in vivo* studies that consider the cross-talk among the various tissues. This point has been remarkably illustrated in recent years with the cloning of the *ob* gene and the various roles played by leptin.

Cells of clonal lines fall into three categories: (1) totipotent embryonic stem cells (ES cells) giving rise to embryoid bodies able to generate cells of all lineages; (2) multipotent stem cells that follow myogenic, chondrogenic, osteogenic, and adipogenic pathways; and (3) cells that have been considered as unipotent cells, termed preadipocytes (Table 2). ES cells can differentiate spontaneously into various lineages and, quite recently, conditions to induce an adipocyte lineage and adipocyte formation at a high frequency from ES cells have been described. This provides a means to identify novel regulatory genes implicated in early determination events of adipogenesis (102). So far, most studies on adipogenesis have relied on the use of supposedly unipotent adipoblastic cells and rarely on multipotent cells of mesodermal origin (Table 2). Recent evidence indicates that some preadipocyte clonal lines still exhibit multipotency. However, the gene(s) that commit progression from the multipotent mesodermal stem cell to the adipoblast stage of development have been not been identified nor have been the factors involved in self-renewal of adipoblast stem cell precursors and specific adipoblast markers.

The process of adipose cell differentiation has been primarily investigated in cells of preadipocyte clonal lines such as 3T3-L1, 3T3-F442A, Ob17, 1246, 3T3-T, and ST13, which are all aneuploid. Adipose precursor cells derived from the stromal-vascular fraction of adipose tissues from various species are diploid but have a limited life span. When transplanted into animals, cells from both sources develop into mature fat cells. *In vitro* they differentiate, in the presence of an appropriate hormonal milieu, to yield cells that have most characteristics of adipocytes, including hormonal responses. However, recent data indicate that one or more transcriptional programs are only activated *in vivo* to generate the full adipocyte phenotype (110).

One of the most exciting findings in the recent years is the possibility, on the one hand, to direct adipogenesis from multipotent cells and, on the other hand, to induce *trans*differentiation into adipocytes

**Table 2** Cellular Models of Adipogenesis

| Cell lines   | Origin   | Phenotypes   | Ref.  |
|--|--|--|-------|
| Totipotent   |  |  |       |
| Embryonic stem cells   | Mouse blastocysts                              | All  | 102   |
| Multipotent  |  |  |       |
| 10T1/2   | Mouse embryo                                   | Muscle cells, white adipocytes, chondrocytes, osteocytes | 3,103 |
| 3T3-F442A  | Swiss mouse embryo (3T3 cells)                 | White adipocytes, osteocytes                             | 104   |
| Unipotent  |  |  |       |
| 3T3-L1   | Swiss mouse embryo                             | White adipocytes   | 3,103 |
| Ob17   | Epididymal fat pad of ob/ob mice               | White adipocytes   | 3,103 |
| BFC-1  | Mouse BAT                                      | White adipocytes   | 3,103 |
| TA1  | Subclone of 10 T1/2 treated with 5-azacytidine | White adipocytes   | 3,103 |
| Lisa-2   | Human liposarcoma                              | White adipocytes   | 105   |
| BIP  | Bovine intramuscular WAT                       | White adipocytes   | 106   |
| Cell strains   |  |  |       |
| Subcutaneous, epididymal, retroperitoneal WAT of newborn and adult | Rat  | White adipocytes   | 3,103 |
| Bone marrow  | Rat  | White adipocytes   | 3,103 |

from supposedly unipotent cells. Clonal 3T3-F442A preadipocytes can undergo osteoblastic differentiation after exposure to bone marrow morphogenetic protein-2 (104), whereas human osteosarcoma SaOS-2B10 and MG-63 cells as well as murine stromal BMS2 cells can convert to adipose cells (111,112). Cells that exhibit the characteristics of mesenchymal stem cells have been isolated from human bone marrow. These cells differentiate into the adipose chondrocytic and osteocytic lineages, and individual stem cells retain their multilineage potential (107). Even more striking, depending on the composition of the culture medium, stromal-vascular cells from human WAT can be directed to undergo differentiation into adipogenic, chondrogenic, osteogenic and myogenic cells (25). However, it remains to be shown that the latter observations relate to the presence of individual stem cells and

not to that of multiple lineage-committed cells present in the cell population. *Trans*differentiation appears also possible as both myoblasts of C2C12 clonal line and muscle satellite cells are able to convert significantly to adipose cells upon exposure of the cells to long-chain fatty acids or BRL49653, a ligand agonist of PPAR $\gamma$  (113).

Wnts, which are secreted signaling proteins regulating developmental processes, behave as molecular switch, likely through Wnt 10-b, which governs adipogenesis. Active Wnt signaling is required for commitment to the myocyte lineage, whereas prevention of active Wnts signaling pathway triggers adipogenesis (114). Collectively, these observations emphasize that cell plasticity is more important than anticipated and that unipotentiality should be better and more cautiously defined *in vitro* as the only pathway that

a precursor cell can follow in response to a given hormonal milieu.

## B Sequential Events of Adipogenesis

### 1 General Considerations

Adipogenesis is a multistep process characterized by a sequence of events during which adipoblasts divide until confluence (Fig. 3). Adipoblasts are fibroblast-like cells, and no specific markers of that stage have been identified so far. Growth arrest at the G1/S stage of the cell cycle (stage 2), rather than contact among arrested cells, is necessary to trigger the process of cell commitment to preadipocyte which is associated with the induction of genes such as those encoding  $\alpha 2$  chain of collagen VI (A2COL6/pOb24), clone 5, adipocyte differentiation related protein (ADRP), lipoprotein lipase (LPL) mRNA, and LPL activity. The regulation of expression of these genes takes place primarily at a transcriptional level and does not require the various hormones which, in contrast, are required for subsequent steps. The dramatic changes observed in cell morphology are associated with alterations in extracellular matrix components. The expression of late and very late markers is associated with limited growth resumption of these committed early marker-expressing cells. At least one round of cell division has been consistently observed in rodent cells, and this process of clonal amplification of preadipocytes (defined as postconfluent mitoses or clonal expansion) is limited both in magnitude and duration. Terminal differentiation to adipocytes (defined by the emergence of GPDH activity and triacylglycerol accumulation) then takes place, provided that cell contacts exist and that cells are exposed to the appropriate hormonal milieu. Mature fat cells then become able to secrete dozens of proteins. These observations made *in vitro* are consistent with those made *in vivo* concerning the relationships in rodent adipose tissue between cell proliferation and differentiation. Although the presence of adipoblasts cannot be excluded, the differentiation process of adipose precursor cells isolated from fat tissue corresponds primarily to the sequence: preadipose cell (preadipocyte)  $\rightarrow$  immature adipose cell  $\rightarrow$  mature adipose cell (adipocyte). When seeded at clonal densities, stromal-vascular cells from rat perirenal and epididymal fat depots show varying capacities for replication and differentiation, irrespective of donor age. At any given age, stromal-vascular cells from perirenal fat tissue showed a greater proportion of clones with a high frequency of differentiation than in

epididymal fat tissue (3). Both in rat for the perirenal and epididymal adipose tissues (115) and in human for the subcutaneous adipose tissue (23), aging is associated with a decrease in the proportion of cells undergoing differentiation.

### 2 Receptor Equipment and Adipogenesis

Table 3 summarizes the receptor composition of adipoblasts, preadipocytes, and adipocytes. Not unexpectedly, preadipocytes express the cognate receptors of adipogenic hormones required for subsequent events to occur. The alterations in hormone responsiveness as a function of differentiation correspond to a critical "time window" of action in preadipocytes during which adipogenic hormones induce the terminal differentiation process.

Growing adipoblasts express cell surface receptors of the major prostaglandins which are produced by these cells [prostacyclin ( $PGI_2$ ), prostaglandin  $F_{2\alpha}$  ( $PGF_{2\alpha}$ ), and prostaglandin  $E_2$  ( $PGE_2$ )] as well as nuclear receptors recognizing glucocorticoids,  $T_3$ , and retinoic acid (RA). The adenosine receptor  $A_2$  subtype, the prostacyclin IP receptor, and the  $PGE_2$  receptor (EP4 subtype), all positively coupled to adenylate cyclase, are present in preadipocytes and then become expressed at low levels, if any, in adipocytes, consistent with the importance of the protein kinase A (PKA) pathway to trigger terminal differentiation of preadipocytes (see Sec. IV. C. 1). These observations are also consistent with those made in the comparative study of prostaglandin sensitivity of adenylate cyclase of rat primary preadipocytes and isolated adipocytes which show that  $G_i$  activity is reduced or absent in preadipocytes (116). The EP3 subtype ( $\alpha$ ,  $\beta$ , and  $\gamma$  isoforms) of the  $PGE_2$  receptor and the adenosine receptor  $A_1$  subtype (118–121), all coupled negatively to adenylate cyclase, then become detectable in adipocytes, consistent with the well-known antilipolytic effects of  $PGE_2$  and adenosine observed in mature fat cells. Commitment to preadipocytes is characterized by the emergence of the cell surface receptor of leukemia inhibitory factor (LIF) as well as that of nuclear receptor PPAR $\delta$  and transcription factors C/EBP $\beta$  and  $\delta$  (117).

Of growing interest are cell surface proteins which are membrane associated or potentially secreted (122,123). Pref-1 and dlk proteins are members of the EGF-like homeotic family of proteins and are polymorphic variants of the same dlk

**Figure 3** Multiple stages of adipose cell differentiation. The scheme is based on data obtained with 3T3-L1, 3T3-F442A, and Ob17 cells as well as with rodent adipose precursor cells. Based upon data obtained in cells of clonal lines and primary cultures.

<sup>a</sup> Abbreviations: LIF-R, leukemia inhibitory factor receptor; IP-R, prostacyclin receptor; FP-R, PGF<sub>2</sub> $\alpha$  receptor; EP-R, PGE<sub>2</sub> receptor; A<sub>1</sub>-R and A<sub>2</sub>-R, adenosine (subtypes 1 and 2) receptor; GH-R, growth hormone receptor; IR, insulin receptor; pref-1/dlk, preadipocyte factor-1/delta like factor; GR, glucocorticoid receptor; AR, androgen receptor; ER, estrogen receptor; PR, progesterone receptor; RAR, retinoic acid receptor; RXR, retinoic X receptor; TR, triiodothyronine receptor; PPAR, peroxisome proliferator-activated receptor; AhR, arylhydrocarbon receptor; Arnt, Ahr nuclear translocator; CREB, cAMP response element-binding protein; C/EBP, CCAAT/enhancer binding protein; ADD1/SRBP-1c, adipocyte determination and differentiation factor-1/sterol regulatory element binding protein-1c; Id, inhibitory protein of DNA binding.

<sup>b</sup> The signs refer to comparative levels of each mRNA or protein between adipoblasts, preadipocytes, and adipocytes, i.e., the absence (—) or the presence at very low levels (+), low levels +, or higher levels ++ and +++.

<sup>c</sup> Not determined.

gene. The soluble form of pref-1/dlk is present in preadipocytes and acts as a negative regulator of adipogenesis (123). In contrast, Notch-1, another transmembrane protein of the family of EGF-like homeotic genes, appears required for adipogenesis as antisense Notch-1 prevents PPAR $\delta$  and PPAR $\gamma$  expression (144).

### C Adipogenic Factors and Second-Messenger Pathways

The responsiveness of preadipose cells to external signals may vary according to differences in the stage of adipose lineage at which clonal lines have been established and that at which cells of a given line are exposed

to various agents. Moreover, the requirement for adipogenic hormones shows differences between clonal and primary preadipocytes. Last but not least, serum-supplemented media are (too) often used, as many serum components are uncharacterized and thus not controllable, this renders comparisons between various studies rather difficult. The use of serum-free, chemically defined media appears more appropriate. In serum-free conditions, the most common requirements of primary preadipocytes appear to be glucocorticoids, IGF-1, and insulin. Clonal preadipocytes also require GH and T<sub>3</sub> and/or retinoids. A salient feature is that the required hormones have to be present simultaneously within a physiological range above threshold concentrations to trigger terminal differentiation.

### 1 Glucocorticoids, cAMP-Elevating Agents, and Leukemia Inhibitory Factor

Glucocorticoids, including the synthetic glucocorticoid dexamethasone, stimulate the differentiation of clonal preadipocytes and that of primary preadipocytes of various species including human, and are presumed to act via their cognate nuclear receptor GR. Dexamethasone reduces the expression of *pref-1/dlk*, a negative regulator of adipogenesis (145). Glucocorticoids are known to increase on a long-term basis the production confined to preadipocytes of prostacyclin, a potent adipogenic hormone (146,147). Dexamethasone is also known to upregulate the expression of C/EBP $\delta$  (148), possibly through prior production of prostacyclin, as carbacyclin—a stable analog of prostacyclin—can substitute for glucocorticoids in promoting adipogenesis (146).

Prostacyclin and carbacyclin, through binding to their cognate receptor IR-R, raise cAMP levels and induce intracellular mobilization of calcium (149). The critical role of prostacyclin as a locally produced hormone raising cAMP and Ca<sup>2+</sup> levels cannot be dissociated from the developmental stage of the cells at which the effectors trigger transducing pathways. First, cAMP promotes the initiation of differentiation of 3T3-F442A preadipocytes but inhibits the late stage(s) of this process (150). Second, the Ca<sup>2+</sup>-calmodulin-sensitive protein kinase II, which is required for the differentiation of 3T3-L1 preadipocytes, exhibits at an early stage within a few hours two temporally distinct phases of activity after stimulation of adipogenesis. It is likely that the time frame of exposure of clonal preadipocytes to calcium ionophores, i.e., the developmental stage at which the cells respond, explains the inhibitory or stimulatory effect previously reported (151). Synthetic

cAMP analogs and methylisobutylxanthine, which increases cAMP levels, trigger adipogenesis. Enhancing cAMP levels upregulates rapidly the expression of the critical early transcription factors C/EBP $\beta$  and C/EBP $\delta$  (152).

In addition to activation of the PKA pathway, activation of leukemia inhibitory factor receptor (LIF-R) by LIF, which is exclusively produced and released by preadipocytes, upregulates also C/EBP $\beta$  and C/EBP $\delta$  via the extracellular signal-regulated kinase (ERK) pathway (117). Both pathways share CREB/ATF-1 as common downstream effectors that upregulate both C/EBPs and promote adipogenesis (153).

### 2 IGF-1, Insulin, and Lysophosphatidic Acid

IGF-1 has been shown to stimulate adipogenesis of clonal mouse 3T3-L1 preadipocytes and primary preadipocytes (rat, rabbit, porcine). In addition to IGF-1, clonal and primary preadipocytes also secrete insulinlike growth factor-binding proteins (IGFBPs) as a function of differentiation (39,40). The IGF-1/IGFBPs system is assumed to act in a paracrine/autocrine manner upon GH stimulation, although conflicting results have been reported with respect to the adipogenic activity of GH in vitro (see Sec. IV.C.3). In addition to its well-known effect on lipogenesis, insulin can now be considered as triggering adipogenesis, and targeted invalidation of the insulin receptor in 3T3-L1 preadipocytes impairs their ability to differentiate into adipocytes (154).

Both IGF-1 and insulin stimulate Ras, which activates the ERK pathway, consistent with the induction of adipogenesis by ectopic expression of Ras in the absence of hormonal stimulation (155). Insulin upregulates prenylation of Ras and Rho protein, and this covalent modification ensures proper phosphorylation and activation of cAMP-responsive element binding protein (CREB) which is required for adipogenesis (135,153,156). The phosphoinositide (PI)3-kinase/protein kinase B(PKB also termed Akt)/p70S6 kinase pathway is also implicated in insulin-dependent events. Ectopic expression of PKB and activation of PI-3 kinase are required for adipogenesis (157,158), consistent with the impairment of this process by inhibition of PI-3 kinase (159). Growth-arrested preadipocytes respond to IGF-1 by stimulation of the ERK pathway, and this activation disappears rapidly during terminal differentiation triggered by adipogenic factors (160). Shc, an SH2 domain-containing protein that is a direct substrate for the tyrosine kinase activity of the IGF-1 receptor, is implicated in this loss of IGF-1 response, whose relationships with postconfluent mitoses remain

to be shown (161). Taken together, there is a critical and early window of time during which the ERK pathway is triggered in preadipocytes through binding of IGF-1, insulin, LIF, and prostacyclin to their cognate receptors. This time frame is critical since PPAR $\gamma$ , which appears after PPAR $\delta$ , C/EBP $\beta$  and C/EBP $\delta$  during the differentiation process, is in contrast inhibited by direct phosphorylation of Ser112 by ERK $_1$  and ERK $_2$  (162,163). Lysophosphatidic acid (LPA) is a bioactive phospholipid which, upon release from adipocytes stimulated by  $\alpha$ 2-adrenoreceptor agonists, increased proliferation and spreading of preadipocytes through a Ca $^{2+}$ -independent phospholipase A2 event (164,165). The endothelial differentiation gene-2 receptor appears involved in these effects through the Ras/ERK and the p21 $^{rhoA}$ /cytoskeleton pathway, respectively (166). Thus it is assumed that the mitogenic and paracrine effect of LPA is implicated in adipocyte hyperplasia.

### 3 Growth Hormone and Prolactin

Growth hormone triggers IGF-1 gene transcription, IGF-1 secretion, and adipogenesis of 3T3-F442A and Ob1771 preadipocytes (167,168). GH promotes also diacylglycerol production from phosphatidylcholine breakdown and thus activates protein kinase C (PKC). PKC activators can substitute for GH in modulating cell proliferation, but the presence of IGF-1 is still required for adipogenesis (169). To add to this complexity, it appears that the Janus kinase/Signal transducers and activators of transcription (JAK-STAT) signaling pathway via STAT5 is also implicated in transducing GH-dependent signals during the initiation of 3T3-F442A preadipocyte differentiation (170). This conclusion is in agreement with the generation by homologous recombination of GH receptor-deficient mice or STAT5a- and STAT5b-deficient mice in which fat deposit was reduced (171).

Despite all these observations, the role of GH in adipogenesis remains somewhat confusing. In rat primary preadipocytes, although GH increases IGF-1 production and although IGF-1 promotes cell proliferation, GH still exhibits antiadipogenic properties independent of IGF-1 mitogenic activity (172). This inhibition appears to be due to the maintenance of high levels of pref-1 (173). To reconcile conflicting data in GH action, it is assumed that clonal and primary preadipocytes represent early and late stages of the differentiation process, respectively, as primary preadipocytes should have been previously exposed to GH and, "primed" in vivo. Prolactin stimulates in prolactin receptor-expressing fibroblasts the expression of C/

EBP $\beta$ , PPAR $\gamma$ , and adipogenesis (174), but its adipogenic activity on authentic target cells, i.e., preadipocytes, remains to be shown.

### 4 Tri-iodothyronine and Retinoids

Tri-iodothyronine appears to be required for the differentiation of clonal preadipocytes (127,175). This requirement remains questionable, as no obvious requirement for T $_3$  is observed in primary preadipocytes isolated from pig, rat, rabbit, and human, suggesting as for GH that prior exposure to T $_3$  in vivo has "primed" the cells (3,176).

The ability of retinoic acid (RA) and synthetic retinoids to promote or inhibit differentiation processes has been recognized for several years. At supraphysiological concentrations, RA inhibits adipogenesis of clonal and primary preadipocytes via RA receptors (RARs). Inhibition appears to take place at an early stage, i.e., through C/EBP $\beta$  repression (177). In contrast, at concentrations close to the K $_d$  values of RARs, RA and retinoids behave like potent adipogenic hormones in triggering the differentiation of Ob1771 preadipocytes and primary rat preadipocytes (126).

### 5 Fatty Acids and Metabolites

Both long-chain FA (saturated, unsaturated, nonmetabolizable) and peroxisome proliferators, which are like FA amphipathic carboxylate molecules, are able in clonal preadipocytes to act like hormones, by activating the transcription of several lipid-related genes and promoting adipogenesis in synergy with other adipogenic factors (57,178). Similar observations have been made in rat and human preadipocytes. Moreover, the main adipogenic component of serum is arachidonic acid (ARA) (179). Its adipogenic effect is blocked by cyclo-oxygenase inhibitors, suggesting that prostanoid(s) are involved. Prostacyclin (used in the form of stable carbacyclin) is the only active prostanoid in promoting adipogenesis (180), and this stimulatory effect can be extended to rat and human primary preadipocytes (149). In addition to binding to the cell surface prostacyclin receptor (IP-R), carbacyclin binds to the nuclear receptor PPAR $\delta$  (181). This suggests a dual role of ARA—directly, as agonist of PPARs, and indirectly, as a precursor of prostacyclin then active via IP-R at the cell surface and via PPAR $\delta$  within the nucleus. The natural ligand(s) of PPAR $\delta$  may differ from prostacyclin, but this prostanoid along with PGE $_2$  and trace levels of PGF $_{2\alpha}$  is the only metabolite of ARA so far characterized in preadipocytes (182).

## 6 Angiotensin II

Angiotensin II (AngII) is secreted from WAT *in vivo* and also from adipocytes *in vitro*. WAT represents an important extrahepatic source of angiotensinogen which accumulates and is released in late differentiated cells (183,184). AngII binds to its cognate receptor(s) in adipocytes, which respond by increased lipogenesis (185) and release of prostacyclin (186). The renin-angiotensin system (RAS), which gives rise to AngII from angiotensinogen, is present in WAT and adipocytes from rodents and human, suggesting that RAS plays a role in WAT development (187). An autocrine/paracrine mechanism has been shown to operate *in vivo*, leading to an increased fat mass due to triglyceride accumulation in adipocytes (188).

## 7 Extracellular Matrix Components and the Plasminogen Cascade

Extracellular proteolysis mediated by plasma kallikrein and the substrate plasminogen is required for adipogenesis, presumably through the formation of plasmin which subsequently cleaves fibronectin. Inhibition of generated plasmin by  $\alpha$ -2-antiplasmin but not by plasminogen-activator inhibitor-1 (PAI-1) impaired adipogenesis. Early inhibitory events are then taking place in preadipocytes, i.e., blockade of rounding up and C/EBP $\beta$  expression. Since fibronectin is a component of the preadipocyte extracellular matrix, it is assumed that activation of the plasminogen cascade induces cytoskeleton remodeling and/or bioavailability of IGF-1, which are required for later events of adipogenesis (189).

## D Antiadipogenic Factors

Various factors that decrease or abolish differentiation of adipose precursor cells have been reported, including a variety of cytokines (TNF $\alpha$ , IL-1, IL-6), platelet-derived growth factor (PDGF), and TGF $\beta$ . The most intriguing results are those obtained in preadipose cells with TGF $\beta$  since, except for pig preadipocytes (3), terminal differentiation appears irreversibly blocked after its removal in contrast to various other factors where partial or complete recovery of the differentiated phenotype is observed (190). The situation remains unclear with regard to fibroblast growth factor (FGF) and epidermal growth factor (EGF), which have been claimed to be either inhibitory or without effect, depending on the origin of target cells. *In vivo*, subcutaneous administration of EGF to newborn rats results in a large decrease in the weight of inguinal fat pads, which suggests the delayed formation of adipocytes from

preadipocytes (3). A downregulation of PPAR $\gamma$  gene expression appears to contribute to the antiadipogenic effect of TNF $\alpha$  (191). The inhibitory effect of TNF $\alpha$  on adipocyte differentiation is also observed if it is administered at an early stage. TNF $\alpha$  disrupts the normal pattern of expression of p107 and p130 proteins, two members of the retinoblastoma family of proteins, and leads to a complete block in clonal expansion (192).

Among flavonoids, which are polyphenolic compounds that exist widely in plants, genistein inhibits both adipoblast proliferation and adipogenesis (193). Many fat-soluble vitamins, as well as dehydroepiandrosterone and some structural analogs, are also known to abolish terminal differentiation of clonal preadipocytes (3,194). Retinoids have been reported to inhibit differentiation, but the supraphysiological concentrations used in those studies raise serious doubt about their physiological relevance. So far, one of the most interesting antiadipogenic agent appears to be PGF $_{2\alpha}$ . It inhibits differentiation of clonal and primary preadipocytes, most likely via the cognate cell surface PGF $_{2\alpha}$  receptor (FP-R) (120). Inhibition of adipogenesis by PGF $_{2\alpha}$  appears to occur through ERK-mediated phosphorylation of PPAR $\gamma$ , thus inhibiting its transcriptional activity (163). Nevertheless, this inhibition is rather unlikely to take place during the differentiation process, as PGF $_{2\alpha}$  is only synthesized in preadipocytes at trace levels compared to prostacyclin (182) and as its effect is fully reversed by carbacyclin (190).

## V MOLECULAR MECHANISMS OF ADIPOGENESIS

### A Transcriptional Activators and Repressors of Adipogenesis

Postmitotic growth arrest is followed by terminal differentiation of preadipocytes to adipocytes (stages 4 and 5) (Fig. 3), which are states of irreversible growth arrest as mature fat cells do not divide. Upon activation by FA or specific agonists, PPAR $\delta$  mediates postconfluent mitoses in a cAMP-dependent manner (195,196). As PPAR $\delta$  is implicated in the activation of a limited set of genes including PPAR $\gamma$  (196–198) and as PPAR $\gamma$  induces cell cycle withdrawal and irreversible growth arrest, it would appear that PPAR $\delta$  and PPAR $\gamma$  are playing both opposite and complementary roles (199). Recent evidence indicates that PPAR $\gamma$  is essential for cardiac and adipose tissue development during mouse embryogenesis (200,201). Various redundant signaling pathways as well as several transcription factors are converging to upregulate PPAR $\gamma$ , which acts as com-

mon and essential regulator of terminal events of adipogenesis and also as a regulator of adipocyte hypertrophy (Fig. 4), emphasizing the importance of adipose tissue development to ensure physiological functions.

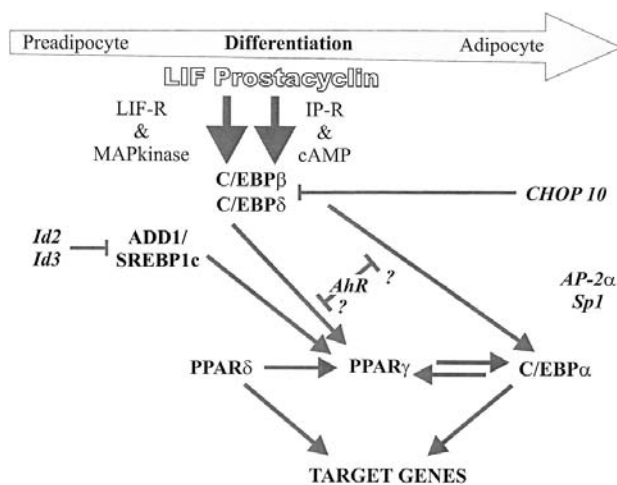

Forced ectopic expression of C/EBP $\beta$  in cells of various clonal lines of fibroblastic origin, which normally express very low levels of C/EBP $\beta$ , C/EBP $\alpha$ , and PPAR $\gamma$ , induces adipogenesis, with C/EBP $\delta$  acting in synergy with C/EBP $\beta$  (136). In most studies, significant adipogenesis of stable fibroblast transfectants requires the simultaneous presence of PPAR $\gamma$  ligands, in contrast to authentic preadipocyte target cells (3T3-L1, 3T3-F442A, Ob1771 cells), suggesting that authentic differentiating cells are able to express PPAR $\gamma$  and simultaneously to synthesize uncharacterized PPAR $\gamma$  ligand(s).

Intracellular pathways that upregulate in clonal preadipocytes the expression of C/EBP $\beta$  and C/EBP $\delta$  are also able to trigger adipogenesis. It has been shown that preadipocytes have the unique capacity both (1) to synthesize and secrete LIF and prostacyclin, and (2) to express at the same time their cognate cell surface receptors LIF-R and IP-R. Binding to LIF-R and IP-R triggers the ERK and PKA pathways, respectively, which in turn activate the critical expression of C/EBP $\beta$  and C/EBP $\delta$  and promote adipogenesis (117,152). Signal transduction proteins involved in the upregulation of transcriptional activators may also regulate adipogenesis as reported for ectopic expression of the differentiation-enhancing factor-1 (DEF-1) in NIH-3T3 and

BALB/c-3T3 fibroblastic cells (202). Forced expression of adipocyte determination and differentiation factor-1/sterol regulatory element binding protein-1c (ADD1/SREBP-1c) or ADD-1 403, a superactive truncated form of ADD-1, upregulates the expression of PPAR $\gamma$  in 3T3-L1 cells (203). This transcription factor is expressed early during adipogenesis and is part of the SREBP family, which are synthesized as membrane-bound precursors released through proteolytic processes and translocated into the nucleus. ADD-1/SREBP-1c appears to be positively controlled by insulin, thus establishing a link between this transcription factor and carbohydrate availability (204). Other stable transfectants able to express constitutively various components of the insulin signaling pathways have also been shown to trigger adipogenesis, i.e., activated Ras mutants, Raf, PI3-kinase, p70S6 kinase, and more recently PKB (c-Akt), which appears to act downstream of PI3-kinase but upstream of p70S6 kinase (205).

Taken together, these studies emphasize the existence of redundant signals of adipogenesis and the wide panoply of transcription factors and their link with the nutritional status, i.e., first PPARs and fatty acid availability and second ADD-1 and carbohydrate availability. It is important to note that heterozygous PPAR $\gamma$  +/– mice appear, at least in part, protected from increased fat mass upon high-fat feeding as compared to wild-type mice. Adipocyte size is significantly smaller in these mice with no change in adipocyte number (206). Thus, it cannot be excluded that subtle alterations between individuals in the activity level of some components regulating expression and/or activity of PPAR $\gamma$  may bring significant differences in fat tissue mass.

Transcriptional repression may involve passive mechanisms by which the negative regulator binds to activators and forms inactive heterodimers, thus playing a dominant-negative role. Alternatively, active repression may occur when the repressor binds to *cis*-acting sequences of a gene promoter and interferes with the transcriptional machinery. Both types of repression take place in preadipocytes (Fig. 4). Passive repression by Id2 and Id3 proteins (inhibitors of DNA binding) has been reported. Id2 and Id3 decrease dramatically during adipogenesis, and forced expression of Id3 protein blocks this process (141). Direct interaction of Id2 and Id3 with ADD-1 takes place, and this postulated heterodimerization decreases the functional capacity of ADD-1 to upregulate genes controlled transcriptionally by ADD-1 (142). C/EBP homologous protein-10 (CHOP-10/GADD153) is a member of the C/EBP family and acts also as a dominant-negative inhibitor

of transcription (207). CHOP-10 sequesters C/EBP $\beta$  by heterodimerization. As preadipocytes reach the S phase, which precedes postconfluent mitoses, downregulation of CHOP-10 allows the release of C/EBP $\beta$ , which binds to C/EBP $\alpha$  promoter and activates C/EBP $\alpha$  gene expression (208). Another member of the basic helix-loop-helix (bHLH) proteins is the arylhydrocarbon receptor (AhR). Although a physiological ligand of AhR has yet to be identified, it binds 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD) and related compounds. After ligand binding, AhR dissociates from cytosolic complex and translocates to the nucleus where it heterodimerizes with the AhR nuclear translocator (Arnt). This heterodimer then binds to xenobiotic response

element (XRE) present within the promoter region of various genes. Both AhR and Arnt proteins are present in adipoblasts and disappear rapidly in differentiating preadipocytes. TCDD appears effective only when added at the adipoblast or at the early preadipocyte stage and decreases C/EBP $\alpha$  and PPAR $\gamma 2$  but not C/EBP $\beta$  and C/EBP $\delta$  levels (131).

TCDD clearly inhibits adipogenesis through the AhR pathway, as shown in AhR $-/-$  mouse embryo fibroblasts (132). Moreover, TCDD increases phosphorylation of the repressor chicken ovalbumin upstream promoter transcription factor (COUP-TF), thus preventing PPAR $\gamma$ /RXR $\alpha$  to bind to their response element DR-1 (133). In addition, Arnt may

play a role independent of its binding to AhR as it heterodimerizes with hypoxia inducible factor-1 $\alpha$  (HIF-1 $\alpha$ ), which is also induced at early stage of adipogenesis (134). Active repressors which bind to regulator sequences of promoters of the C/EBP $\alpha$  promoter have also been reported. Two repressor-binding sites are present in the C/EBP $\alpha$  promoter and are recognized by an isoform of the AP-2 transcription factor family, termed C/EBP $\alpha$  undifferentiated protein (CUP/AP-2 $\alpha$ 1). This factor inhibits the transcriptional activation of the C/EBP $\alpha$  gene and thus may be implicated in the maintenance of this gene in a repressed state as well as in the

maintenance of the preadipocyte stage (140). A member of the Sp family, Sp1, binds to a consensus Sp-binding site of C/EBP $\alpha$  unique among the promoters of adipocyte genes. By doing so, it prevents the *trans*-activation of C/EBP $\alpha$  gene by C/EBPs. Raising cAMP levels cause downregulation of Sp1, consistent with the initial PKA-mediated events of adipogenesis (209).

The GATA family of transcription factors, i.e., GATA-2 and GATA-3 expressed in white adipocyte precursors and testis but not in BAT or other organs, are repressing adipogenesis, at least in part by inhibiting PPAR $\gamma$ 2 gene expression through binding to consensus

DNA sequence present in its promoter. Consistently, GATA-3-deficient ES cells exhibit enhanced capacity to differentiate into adipocytes (143). It thus seems that passive mechanisms, which are functional at the time of C/EBP $\beta$  and ADD-1 expression, are reinforced by specific and active mechanisms. Both mechanisms then become nonfunctional at the onset of terminal differentiation, which leads to the adipocyte phenotype.

## **B WAT Development After Gain of Function or Loss of Function**

The recognition of the prime importance of an adequate mass of WAT, coupled with the dramatic improvement of our understanding of regulatory mechanisms of adipogenesis, have led to numerous *in vivo* gain- or loss-of-function experiments.

In most cases of gain-of-function experiments (Table 4), use was made of the adipocyte-specific promoter/enhancer of the ALBP gene, which allows targeted expression in WAT and BAT of various genes of interest. Compared to wild-type control mice, and in agreement with their postulated physiological role, overexpressing the lipolytic  $\beta$ 1-adrenoreceptor (210) or overexpressing the antilipolytic human  $\alpha$ 2-adrenoreceptor (on a  $\beta$ 3 adrenoreceptor  $-/-$  background) (211) leads to a decreased or increased fat mass, respectively. Overexpression of agouti (213), angiotensinogen (188) (likely acting in a paracrine/autocrine manner), or the glucose transporter-4 (GLUT-4) (62) enhances fat mass. A high-fat diet magnifies this weight increase. Notably, depending on the overexpressed gene, fat mass alterations are due to change in fat cell number or in fat cell size.

The most dramatic effect of overexpression is observed in the case of genes encoding transcription factors. Mice overexpressing A-ZIP/F protein, a dominant-negative protein which binds transcription factors of the C/EBP and *c-jun* families, are fat-free and exhibit the features of human lipoatrophic diabetes (214) whereas mice overexpressing ADD-1/SREBP-1c exhibit many of the features of human congenital generalized lipodystrophy (215). Overexpression of the transcription factor FOXC2 in adipose tissue leads to a lean and insulin sensitive phenotype. Interestingly, the sensitivity of the  $\beta$ -adrenoreceptor/cAMP/PKA pathway is also increased although the relative importance of  $\beta$ 1-,  $\beta$ 2-, and  $\beta$ 3-adrenoreceptor remains to be investigated. As FOXC2 gene levels are upregulated by high-fat feeding and as transgenic mice exhibit resistance to diet-induced obesity, it appears that FOXC2 overexpression counteracts the major symptoms associated with obesity (216).

Adipose tissue development can be also impaired or enhanced after gene invalidation (Table 5). For the sake of clarity, genes expressed in the central nervous system have been excluded, the invalidation of which has revealed a key role in the control of body weight regulation and/or food intake. In a few cases, KO mice exhibit smaller size than wild-type mice, with a disproportionate decrease in fat mass, i.e. PPAR $\delta$   $-/-$ , Hmgic  $-/-$ , RII $\beta$   $-/-$ , and GLUT-4  $-/-$  mice. Surprisingly, although lipolysis is associated with phosphorylation of hormone-sensitive lipase and that of perilipin, an adipocyte protein coating triglyceride droplets, only the invalidation of perilipin leads to resistance to diet-induced obesity (217,218). The invalidation of diacylglycerol acyltransferase gene, which encodes a key enzyme implicated in triglyceride synthesis, leads to the same phenotype but also to an unexpected increase in energy expenditure (219). An increase in energy expenditure is also observed in protein tyrosine phosphatase-1B-deficient mice which exhibit increased insulin sensitivity and resistance to diet-induced obesity (220,221). The invalidation of the gene encoding the cell surface receptor of very low density lipoproteins leads to increased plasma postprandial triglycerides and, on a long-term basis, to resistance to diet-induced obesity (229). Of interest is the invalidation of mitochondrial acetylCoA carboxylase-2, as the decrease of malonyl-CoA levels is associated with higher fatty acid oxidation in muscles and lower fat tissue mass despite hyperphagy (222).

Some rationale emerges with respect to invalidation of genes encoding C/EBPs and nuclear receptors of the PPAR family and the gene encoding Hmgic, a partner of the transcriptosome, as reduced fat mass is observed as compared to wild-type mice (230–235). That C/EBP $\beta$   $-/-$  C/EBP $\delta$   $-/-$  mice exhibit reduced fat mass with normal levels of C/EBP $\alpha$  and PPAR $\gamma$  strongly suggests that alternative routes to upregulate PPAR $\gamma$ , i.e., PPAR $\delta$  and ADD-1/SREBP-1c, are functional in these double KO mice (233). Interestingly, the time-dependent specific excision of RXR $\alpha$  from WAT and BAT leads to impaired lipolysis and resistance to diet-induced obesity (234). Despite this wealth of information, data from these various investigations are rather difficult to compare, as WAT cellularity, food intake, energy expenditure and resistance to high-fat diet have not been systematically reported. In summary, it is clear from the data in Tables 4 and 5 that WAT mass can be altered by predicted but also by rather unexpected ways. This situation adds further complexity to devise well-defined molecular targets at the peripheral level, which will prove ultimately to be efficient in treating obese patients.

## Lipolysis and Lipid Mobilization in Human Adipose Tissue

**Dominique Langin and Max Lafontan**

Obesity Research Unit, INSERM U586, Louis Bugnard Institute, Université Paul Sabatier-Centre Hospitalier Universitaire de Rangueil, Toulouse, France

### I INTRODUCTION

Adipose tissue is the body's largest energy reservoir. Energy is stored in fat cells as triacylglycerols (TG). Factors that control the storage and mobilization of TG in adipocytes are important regulators of fat accumulation in various fat areas (1). The major source for adipocyte TG comes from chylomicrons and very low density lipoproteins (VLDL). TG in the lipoprotein particles are hydrolyzed by lipoprotein lipase (LPL) located on the capillary walls of adipose tissue so that nonesterified fatty acids (NEFA) and monoacylglycerol are formed. NEFA are probably taken up by the fat cell through passive and active transport. Indeed, specific NEFA-transporting proteins have been described (2–4). Once taken up by the fat cells, NEFA are esterified to TG. The circulating albumin-bound NEFA can also be taken up by the fat cells and esterified to TG.

Adipose tissue lipolysis, i.e., the catabolic process leading to the breakdown of triglycerides into NEFA and glycerol, is often considered as a simple and well-understood metabolic pathway. However, it is not firmly established what truly sets the rate of adipose tissue lipolysis. Newly released NEFA can be reesterified in the adipocytes. Quantitative studies are lacking in vivo. Catecholamines and insulin represent the major regulators of lipolysis. However, the physiological role of a number of other lipolytic and antilipolytic agents

remains to be elucidated. During lipolysis, intracellular TG undergo hydrolysis through the action of a neutral lipase located inside the fat cell, hormone-sensitive lipase (HSL). NEFA and glycerol leave the fat cells and are transported by the bloodstream to other tissues (mainly liver for glycerol; liver, skeletal muscle, and heart for NEFA). NEFA act as signaling molecules as well as metabolic substrates.

In addition to their role in adipose tissue metabolism, they can regulate glucose utilization in muscle and are important signals to the liver and beta cells as well. Some of the NEFA that are formed during lipolysis do not, however, leave the fat cell and can be reesterified into intracellular TG. The glycerol formed during lipolysis is not reutilized to a major extent by fat cells because they contain only minimal amounts of the enzyme glycerol kinase. In normal-weight man, the mean turnover rate of TG in the total fat mass is ~100–300 g TG per day. An imbalance between hydrolysis and synthesis of TG can be important for the development of obesity. Altered lipolysis could be an element leading to obesity and interindividual variations in AT lipolysis are of importance for the rate of weight loss. Conversely, excessive lipolytic rates, in conjunction with impairment in NEFA utilization by muscle and liver, may be a major contributor to the metabolic abnormalities found in persons with android or upper-body obesity and lead to non-insulin-dependent diabetes mellitus (NIDDM).

**Figure 1** Control of human adipocyte lipolysis. Diagram of signal transduction pathways for catecholamines via adrenergic receptors (AR), atrial natriuretic peptide via type A receptor and insulin. Protein kinases (PKA, PKG, and PKB) are involved in target proteins phosphorylations. HSL phosphorylation promote its translocation from the cytosol to the surface of the lipid droplet. Perilipin phosphorylation induces an important physical alteration of the droplet surface that facilitates the action of HSL and lipolysis. Docking of ALBP to HSL favors the evacuation of NEFA released by the hydrolysis of triglycerides. Question marks show pathways which are still hypothetical or the relevance of which has not been fully demonstrated in human fat cells. Abbreviations: AC, adenylyl cyclase; ALBP, adipocyte lipid-binding protein; AR, adrenergic receptor; FA, fatty acid; GC, guanylyl cyclase; Gi, inhibitory GTP-binding protein; Gs, stimulatory GTP-binding protein; HSL, hormone-sensitive lipase; IRS, insulin receptor substrate; NEFA, nonesterified fatty acid; PDE-3B, phosphodiesterase 3B; PI3-K, phosphatidylinositol-3-phosphatase kinase; PKA, protein kinase A; PKB, protein kinase B; PKG, protein kinase G.

This chapter reviews quantitative and regulatory aspects of lipid mobilization in human adipose tissue. Several hundred articles have been published relating to adipose tissue metabolism. In light of space limitations, we will as often as possible cite reviews that cover a large number of major publications in the area. A diagram of the mechanisms involved in the control of human fat cell lipolysis is given in Figure 1.

## II TRIGLYCERIDE HYDROLYSIS

### A Protein-Lipid Interactions

The hydrolysis of the triglycerides stored in the fat cell lipid droplets is a complex phenomenon. One mole of

triglyceride is broken in a stepwise fashion via diglyceride and monoglyceride intermediates into 3 moles of free fatty acid and 1 mole of glycerol. In vitro, HSL catalyzes the hydrolysis of triglycerides into diglycerides, and diglycerides into monoglycerides. The first step occurs at a 10-fold lower rate than the second step. The enzyme is also responsible for the hydrolysis of cholesterol and retinyl esters. Although HSL has the capacity to hydrolyze monoglycerides in vitro, monoglyceride lipase (MGL) is required to obtain complete hydrolysis of monoglycerides in vivo. It is important to note that MGL also hydrolyzes 2-monoglycerides resulting from the action of lipoprotein lipase. Unlike other known mammalian triglyceride lipases, HSL phosphorylation by protein kinase A

(PKA) leads to an activation of the enzyme. Through modulation of  $0cAMP$  levels, catecholamines and insulin therefore control HSL activity. Three phosphorylation sites have been characterized—Ser<sup>563</sup>, Ser<sup>659</sup>, and Ser<sup>660</sup> (5). The latter two were shown to be responsible for *in vitro* activation of HSL, whereas the role of Ser<sup>563</sup> remains elusive. Activation of the extracellular signal-regulated kinase pathway is able to activate lipolysis by phosphorylating HSL on Ser<sup>660</sup> (6). Whether this pathway is important *in vivo* remains to be demonstrated.

Comparison of *in vitro* and *in vivo* activation of HSL implies that a simple conformational change of phosphorylated HSL leading to a higher affinity for its substrate does not fully account for fat cell lipolysis stimulation. By analogy with other lipases, HSL may exist in two conformational states—an active, open form with exposure of a hydrophobic area that interacts with lipids to unmask the catalytic site, and an inactive, closed form (7). Phosphorylation of HSL would be required to trigger the transition from the closed to the open form. *In vivo*, an important step in lipolysis activation seems to be the translocation of HSL from a cytosolic compartment to the surface of the lipid droplet (8–10). In unstimulated cells, HSL is diffusively distributed throughout the cytosol. Upon stimulation with a beta-adrenergic agonist, the enzyme translocates concomitantly to the onset of lipolysis. This rapid process does not require protein synthesis and apparently does not involve cytoskeleton.

HSL is classically considered as the key enzyme catalyzing the rate-limiting step of adipose tissue lipolysis. Mice lacking HSL are not obese (11,12). Catecholamine-induced lipolysis is markedly blunted as expected, but basal (or unstimulated) lipolysis is unaltered in isolated adipocytes. Accumulation of diglyceride in AT shows that HSL is the rate-limiting enzyme for the catabolism of diglycerides but not triglycerides (13). The data therefore suggest the existence of a triglyceride lipase different from HSL. It is not known whether the high activity of the novel lipase does result from a compensatory mechanism associated with the lack of HSL.

Proper activation of lipolysis relies on proteins that are not directly involved in the catalytic process. Two proteins have recently been shown to interact with HSL: adipocyte lipid-binding protein (ALBP or aP2), and lipotransin (14,15). ALBP is an intracellular fatty acid-binding protein highly expressed in adipocytes. ALBP interacts with HSL N-terminal region and increases the lipolytic activity of HSL through its ability to bind and sequester fatty acids and via specific protein-protein interaction. Consistent with such a role for

ALBP is the observation that ALBP-null mice exhibit decreased lipolytic capacity (16,17). Lipotransin is a member of the katanin family that may dock the protein to the surface of the lipid droplet. The exact contribution of lipotransin to catecholamine lipolytic and insulin antilipolytic effect awaits further studies.

Access to the lipid droplet constitutes another potential mechanism for the control of lipolysis. Perilipins are proteins covering the large lipid droplets in adipocytes (18): They shield stored triglycerides from cytosolic lipases. It has been hypothesized that, upon phosphorylation, perilipins allow access to the lipid droplet and thereby allow lipase to interact with its substrates. In two independent studies, ablation of perilipin results in mice with decreased fat mass and increased lean body mass (19,20). The mice are resistant to diet-induced obesity. Moreover, double mutant *Lepr<sup>db/db</sup>/Plin<sup>-/-</sup>* mice are protected against the obesity phenotype owing to mutation in the leptin receptor. No hepatic steatosis or alteration of the lipid profile was observed, which might be due to the increased metabolic rate of the mutant animals. Basal lipolysis is increased in perilipin-deficient adipocytes, which is in line with a role of perilipin as a suppressor of lipolysis in quiescent cells.

## B Selective Mobilization of Fatty Acid

The selectivity of fatty acid mobilization from rat and human adipose tissue has been reported during fasting *in vivo* (21,22) and during stimulated lipolysis on isolated fat cells (23,24). The composition of NEFA released by adipose tissue was compared to that of the triglycerides from which they originated. For some fatty acids, their percentage in NEFA was different from that in TAG. As a rule, the relative mobilization decreases with increasing chain length for a given unsaturation degree and increases with increasing unsaturation for a given chain length. The contribution of HSL to the selective mobilization was studied using purified HSL and stable lipid emulsions (25,26). The fatty acid specificities of HSL do not seem to be oriented toward a special demand by tissues or toward a preferential sparing of particular fatty acids. Comparison of the relative hydrolysis of fatty acids by HSL and their mobilization rates from adipocytes supports the view that the low mobilization of some fatty acids could derive from a low release of fatty acids by HSL, whereas the high mobilization of other fatty acids seems unrelated to the enzymological properties of HSL. Because HSL can explain only part of fatty acid mobilization, it is possible that ALBP and perilipin contribute to the fatty acid selectivity.

### C Control of HSL Gene Expression

Factors modulating HSL gene expression have been studied in mature adipocytes using murine preadipose cell lines. cAMP and phorbol esters were shown to decrease HSL mRNA and lipase activity levels through independent mechanism, suggesting that sustained activations of protein kinase A and C pathways exert a negative control on HSL gene expression (27). In rodent and human adipocytes, glucose is a positive regulator of HSL expression. Glucose deprivation results in a decrease of HSL mRNA and lipase activity levels (28). The effect of glucose is reversible and is not due to an impairment of the differentiation program. In primary culture of rat adipocytes, prolonged treatment with glucose and insulin results in an increase of basal and stimulated lipolysis and a maintenance of HSL protein levels (29). Long-chain fatty acids do not seem to affect HSL expression.

The 775-amino-acid-long adipocyte HSL is encoded by nine exons spanning 11 kb (30). A short 5' noncoding exon located 1.5-kb upstream of exon 1 contains the transcriptional start site (31). The proximal 5' flanking region contains an E-box that binds upstream stimulatory factors, and two GC-boxes that bind Sp1 and Sp3 (32). The *cis*-acting elements are essential for promoter activity. The E-box also mediates the response to glucose, but the nature of the transcription factor complex responsible for glucose induction is unknown. Besides transcriptional mechanisms, alternative splicing of pre-mRNA has an important role in the regulation of gene expression. An alternatively spliced form of human HSL has been identified in AT (33). In-frame skipping of exon 6 generates a catalytically inactive but phosphorylatable protein. The short-form HSL mRNA represents ~20% of HSL transcripts.

## III MECHANISMS OF THE HORMONAL CONTROL OF LIPOLYSIS

### A G-protein-Coupled Receptors and Adenylyl Cyclase Regulation

Activators and inhibitors of the adenylyl cyclase system and hormones and enzymes controlling intracellular cyclic AMP levels are direct regulators of lipolysis. Intracellular cyclic AMP (cAMP) increases lipolysis while antilipolysis is associated with the lowering of cAMP levels. In vitro studies on human fat cells have established that the tuning of cAMP levels and lipolysis by hormones and paracrine agents is dependent on the balanced cross-talk between stimu-

latory and inhibitory pathways mediating the control of adenylyl cyclase on one hand and fat cell cyclic nucleotide phosphodiesterases (PDEs) on the other. PDEs, by hydrolyzing cAMP and cyclic GMP, are critical in terminating cyclic nucleotide signals and therefore regulate biological processes mediated by second messengers. Activation of adenylyl cyclase activity stimulates the formation of cAMP from ATP. Stimulating receptors coupled to Gs-protein activate adenylyl cyclase while activation of inhibitory receptors coupled to Gi-proteins inhibit the activity of the enzyme.

#### 1 Gs-protein-Coupled Receptors

In human fat cells, both  $\beta_1$ - and  $\beta_2$ -adrenergic receptors are known to stimulate cAMP production and lipolysis in vitro (34) and in vivo (35). The physiological role of the  $\beta_3$ -adrenergic receptor in human adipose tissue remains questionable. The receptor does not contribute to catecholamine-induced lipolysis in human subcutaneous adipocytes (36). The action of  $\beta_3$ -agonists exerting some lipolytic activity in vitro has not been convincingly validated in vivo. Moreover, one of these agonists, CGP 12177, exerts its effect through a so-called  $\beta_4$ -adrenergic receptor effect, which was, in fact, atypical interaction of the drug with  $\beta_1$ -adrenergic receptors (37–40). Confirmation of the lack of  $\beta_3$ -adrenergic effect in humans has also been provided by in vivo studies. During isoproterenol infusion at dosages <200 ng/kg min, there was no evidence for a  $\beta_3$ -adrenergic receptor-mediated increase in human lipolysis, energy expenditure and lipid oxidation (41).

Similar conclusions were obtained when using in situ microdialysis (35). The other hormones which are known to exert lipolytic effects in rodent fat cells through Gs-protein-coupled receptors, such as glucagon, parathyroid hormone, TSH,  $\alpha$ -MSH, and ACTH, are either ineffective or very weak activators of lipolysis in human adipocytes.

#### 2 Gi-protein-Coupled Receptors

In addition to lipolysis-promoting agents neuropeptides, paracrine factors, and autacoid agents (adenosine, prostaglandins and their metabolites) originating from the adipocytes themselves, preadipocytes, endothelial cells, macrophages, and sympathetic nerve terminals are known to negatively control adenylyl cyclase activity and inhibit lipolysis by their interaction with plasma membrane receptors belonging to the seven-transmembrane domain receptor family. The major antilipolytic

pathways involve  $\alpha_2$ -adrenergic receptors,  $A_1$ -adenosine-receptors,  $EP_3$ -prostaglandin  $E_2$  receptors, and neuropeptide Y/peptide YY (NPY-1) receptors. Existence of inhibitory nicotinic acid-receptors is proposed to explain the well-known antilipolytic action of nicotinic acid, but as yet, the receptor protein has not been identified. Antilipolytic responses (initiated by  $\alpha_2$ -adrenergic receptor agonists, prostaglandins, adenosine, NPY/PYY) are less easy to investigate than stimulating effects *in vitro*, and some controversies exist in the design of the experiments and the results.

Recent studies have focused on the diversity and the abundance (number of binding sites) of lipolysis-inhibiting receptors in human fat cells. The human fat cell NPY receptor is an NPY-1 receptor subtype which, when stimulated, sustains a strong antilipolytic effect (42). Adrenaline and noradrenaline have a higher affinity for  $\alpha_2$ - than for  $\beta_1/\beta_2$ -adrenergic receptors, suggesting the existence of a role for the  $\alpha_2$ -adrenergic pathway in the control of lipolysis in humans (43). Concerning adenosine and prostaglandins, these compounds are probably metabolized very rapidly *in vivo* as well as *in vitro* (44,45). Nevertheless, substantial amounts of adenosine were found in the interstitial fluid of adipose tissue (46). Endogenous inhibitory agents may therefore have a stronger effect on TG hydrolysis than previously suspected.  $Gi_2$  is a major transducer of the inhibitory response in adipose tissue, and provides tonic suppression of basal adenylyl cyclase activity *in vivo* (47). The fact that unrestrained fat cell adenylyl cyclase proceeds at increased rates suggests that a certain degree of inhibition might be necessary for fat cell adenylyl cyclase to be susceptible to stimulation. Under *in vivo* conditions, in the presence of the endogenous ligands,  $Gi$ -dependent inhibitory pathways may be undersustained and permanent inhibition, since the inhibitory pathways driven by prostaglandins, catecholamines, and adenosine are always activated at the low concentrations of the agents (43,48). Convincing *in vivo* demonstration of existence of such mechanisms in human adipose tissue is necessary.

## B Tyrosine-Kinase Receptors and Signaling Pathways

Insulin and IGF-1 receptors are prototypic members of this family of receptors that are characterized by an extracellular binding domain, a single transmembrane portion, and a large intracellular catalytic domain. In parallel to their control of glucose uptake by fat cells, insulin and IGF-1 control cAMP levels and lipolysis through PDE3B-dependent degradation of cyclic AMP

to 5'AMP, decrease in cyclic AMP level, inactivation of PKA, and reduced phosphorylation of HSL. Insulin and IGF-1 tyrosine-kinase receptors are coupled to phosphatidylinositol kinase-3 (PI3-K). PI3-K is a heterodimer composed of two subunits: a p85 regulatory subunit, which contains two Src homology 2 (SH2) domains, and one Src homology 3 (SH3) domain, as well as the p110 catalytic subunit. PI3-K possesses both lipid-kinase and serine-kinase activities. The antilipolytic effect of insulin is mediated through the activation of the cGMP-inhibited phosphodiesterase3B (PDE3B).

The activation cascade is rather complex, and some points remain unclear. When insulin binds to its receptor, the receptor is activated by phosphorylation on tyrosine residues, which causes tyrosine phosphorylation on intracellular substrates such as insulin receptor substrate I, II and (IRS-I and II), and binding of the p85 subunit of PI3-K. This binding activates the lipid-kinase, which phosphorylates the phosphoinositol at the D-3 position of the inositol ring. In addition, the PI3-K serine kinase autophosphorylates both the p85 regulatory subunit and the p110 catalytic subunit. This step is followed by PKB/Akt phosphorylation/activation, PDE3B activation, and cAMP breakdown (49).

Recent studies in human adipocytes have shown that PDE3B is associated with the insulin receptor; its association does not appear to be regulated by insulin. Insulin increases binding and capacity of the PI3-K-serine kinase associated with the insulin receptor, leading to an increased phosphorylation and activation of PDE3B (50). cAMP-mediated pathways may either oppose or facilitate the actions of insulin and/or growth factors that signal via receptor tyrosine kinases (51).

## C Other Lipolytic Pathways

### 1 Natriuretic Peptides

A new hormonal lipolytic pathway has been discovered in human fat cells (52). Atrial natriuretic peptide (ANP) and brain natriuretic peptide (BNP) stimulate human fat cell lipolysis as much as isoproterenol. The rank order of potency for stimulation of lipolysis (ANP > BNP > CNP) and the existence of an ANP-induced cyclic GMP production suggested the presence of a functional type A natriuretic peptide receptor in human fat cells. Expression of ANP receptors mRNAs and binding studies have confirmed the presence of type A and C ANP receptors. Activation or inhibition of PDE-3B and inhibition of adenylyl cyclase activity do not modify ANP-induced lipolysis (52). *In vitro* studies have shown that HSL could be phosphorylated by cyclic GMP-dependent protein kinase (53). Cyclic GMP-dependent

activation of protein kinase G and phosphorylation of HSL occur after ANP stimulation in human adipocytes (Sengenès et al., unpublished results). In situ microdialysis experiments have confirmed the potent lipolytic effect of ANP in abdominal subcutaneous AT of healthy subjects, and intravenous administration of ANP promotes a striking rise in plasma levels of NEFA and glycerol in normal and obese subjects (54). ANP-induced lipid mobilizing effect was enhanced after a low-calorie diet in obese subjects (55). These results raise questions about the physiological and/or pathological relevance of this novel lipolytic pathway in normal subjects and obese patients.

## 2 Growth Hormone

Growth hormone (GH) stimulates lipolysis in human adipocytes; however, the exact mechanism of action is not fully clarified. Although GH treatments in adults reduce abdominal obesity and improve insulin sensitivity as well as blood lipid profiles, the physiological contribution of GH to the control of human adipose tissue lipid mobilization has remained elusive and is not yet entirely clear. Recent studies have assessed its role; small physiological GH pulses increase interstitial glycerol concentrations in both femoral and abdominal adipose tissue (56). Moreover, normal nocturnal rise in plasma GH concentrations also leads to site-specific regulation of lipolysis in adipose tissue (57). Of putative pharmacological interest, a small synthetic peptide sequence of human GH (AOD-9041) has been shown to increase human and rodent fat cell lipolysis in vitro. Its efficiency on lipid mobilization has been observed after chronic oral administration in rodents; mechanisms of action remain to be clarified (58).

## 3 Tumor Necrosis Factor- $\alpha$

TNF $\alpha$  is a macrophage product, also released by fat cells, which has been suggested to signal the loss of body weight through the decrease in AT and muscle mass. Macrophages release cytokine(s) in response to lipopolysaccharide that stimulate lipolysis in freshly isolated rat adipocytes. TNF $\alpha$  can account for most of the action on adipocytes. Stimulation of lipolysis by TNF $\alpha$  is not direct, since it becomes apparent only after long-lasting exposure of human and rodent adipocytes to the cytokine (59). Exploration of TNF $\alpha$  mechanisms of action has been performed in rodent fat cells.

To demonstrate the role of the different TNF $\alpha$  receptors in the induction of the lipolytic effects, experiments were performed on preadipocyte cell lines established from wild-type mice (TNFR1  $+/+$  R2  $+/+$ ) and

from mice lacking TNFR1 (TNFR1  $-/-$ ), TNFR2 (TNFR2  $-/-$ ) or both (TNFR1  $-/-$  R2  $-/-$ ). The studies demonstrated that TNF $\alpha$ -induced lipolysis as well as inhibition of insulin-stimulated glucose transport are predominantly mediated by TNFR1 (60). Additional experiments have demonstrated that TNF $\alpha$  could regulate lipolysis, in part, by decreasing perilipin protein levels at the lipid droplet surface (61). Blunting the endogenous inhibition of lipolysis through Gi protein downregulation is another possible mechanism (62). In human fat cells, TNF $\alpha$  activates the three mammalian mitogen activated protein kinases (MAPK) in a distinct time- and concentration-dependent manner. TNF $\alpha$ -induced lipolysis is mediated by only p44/42 and Jun Kinase but not by p38 (63).

## 4 Miscellaneous Agents

Nitric oxide (NO) or related redox species like NO $^+$ /INO $^-$  have been proposed as potential regulators of lipolysis in rodent and human fat cells (64,65). A number of experiments have reported the production by cachexia-inducing tumors of a lipid-mobilizing factor (LMF) that causes immediate release of glycerol when incubated with murine adipocytes. Induction of lipolysis by LMF was associated with an increase in intracellular cAMP levels. LMF has not yet been characterized, but its activity was shown to be attenuated by eicosapentaenoic acid (66). The serum and urine of cachectic cancer patients contain LMF, the activity of which correlated with the extent of weight loss (67).

## IV IN VIVO REGULATION OF LIPOLYSIS IN HUMAN ADIPOSE TISSUE

In normal subjects, regulation of lipolysis in response to feeding, fasting, and exercise is based on HSL expression/activity upon and interactions with several regulators discussed above, principally plasma insulin and sympathetic nervous system activity modulation (68). In humans, several studies have been performed to explore the relationship between HSL expression and lipolytic rate in physiological and pathological situations. In human subcutaneous adipocytes, a good correlation was found between HSL protein and mRNA levels and maximal lipolysis independently of fat cell size (69).

Concerning the various regulators, in vitro studies on human fat cells have established that the tuning of cAMP levels and lipolysis by catecholamines is dependent on the balanced cross-talk between beta- and alpha $_2$ -adrenergic receptor-dependent pathways

(43,70–72). A number of *in vitro* studies have clearly established that the repertoire and the expression level of human adipocyte adrenergic receptors largely differ according to anatomical location of AT depots, sex, and age of the subjects and genetic determinants.

### A Body Fat Distribution and Lipid Mobilization

Body fat distribution differs between normal-weight men and women. A peripheral distribution is usually found in women while a more central one is described in men. Human adipose tissue displays significant regional differences in preadipocyte capacities for replication and differentiation, adipocyte size, basal metabolic activities, and hormonal responsiveness (73). These differences appear to determine regional fat deposition. Adipose site-related differences in the regulation of lipolysis have been shown *in vitro* and *in vivo* in normal-weight subjects (43,71,74–76). Lipolytic response of isolated fat cells to catecholamines is weaker in the subcutaneous gluteal/femoral than in the subcutaneous abdominal and visceral adipose tissue. These site-related differences are more noticeable in women than in men. *In vitro* studies have revealed an enhanced  $\alpha_2$ -adrenergic responsiveness associated with a concomitant decrease in beta-adrenergic responsiveness explains the lower lipolytic effect of catecholamines in gluteal/femoral fat cells of women. Conversely, visceral fat adipocytes exhibit the highest lipolytic responsiveness to catecholamines. *In vitro* studies have shown that concomitant variations in beta<sub>2</sub>- and  $\alpha_2$ -adrenergic sensitivity in adipocytes may be predictive of weight loss during dieting or very low calorie diets (77,78). The mechanisms explaining the regional differences have been investigated *in vitro* (72,79,80). Moreover, microdialysis studies have confirmed the sex-related differences revealed in *in vitro* assays.

Site-related differences are also found in the antilipolytic action of insulin, prostaglandins, and adenosine. *In vitro* studies have demonstrated that regional differences exist in the antilipolytic effects of insulin. Omental adipocytes are less sensitive to the antilipolytic effect of insulin than abdominal subcutaneous adipocytes; mechanisms have been explored (81). Regional heterogeneity of insulin-regulated NEFA release has been confirmed *in vivo*, indicating that visceral adipose tissue lipolysis is more resistant to insulin suppression than is leg lipolysis in humans (82). Whatever the mechanistic interest of the *in vitro* approaches, tissue-specific investigations, using *in situ* microdialysis, must be extended to delineate the physiological relevance of previous studies on antilipolytic agents.

### B Aging

Aging is associated with a diminished ability to mobilize fatty acids and to use fat as a fuel (increase skeletal muscle fatty acid uptake and oxidation) during beta-adrenergic receptor stimulation (83). There is a selective decrease in the beta-adrenergic lipolytic capacity with aging, which may be caused by disturbances at the adrenergic receptor level or at the postadrenergic receptor level. These alterations are independent from the age-expected increase in total adiposity (84). The impairment in sympathetic nervous system (SNS)-mediated lipolysis and fat oxidation may be of importance in the age-related increase in adiposity and obesity.

### C Stress

In diverse stressful conditions such as surgery, trauma, or severe burns, most of the studies have described incremental lipolysis which could be activated to an inappropriate level and lead to excess of plasma NEFA. Activation of lipolysis is due to an increased SNS drive and stress hormones secretion, which both facilitate lipid mobilization and reduce insulin secretion (68,85). Sustained changes in SNS activity or plasma catecholamine levels have commonly been associated with altered beta-adrenergic function in target cells leading to desensitization. Desensitization of beta-adrenergic receptor-mediated lipolysis to catecholamines exposure has extensively been studied *in vitro* (70). Repeated adrenaline treatment has been shown to suppress basal- and adrenaline-stimulated lipolysis in lean and obese subjects. Plasma insulin concentration increased after repeated adrenaline treatment, and could contribute to the loss of adrenaline efficacy (86). The *in vivo* lipolytic response of the AT to adrenaline is desensitized by prior adrenaline exposure (87). However, no cardiovascular desensitization was observed in these conditions. It remains to be established if this phenomenon is related to a noticeable beta-adrenergic receptor desensitization, to the appearance of a change in the balance between beta- and  $\alpha_2$ -adrenergic receptor-dependent effects, or to an incremental increase in plasma insulin level.

### D Exercise

Exercise represents, with fasting, the main physiological situation of increased lipolysis; sustained exercise of moderate intensity is characterized by marked increases in lipolysis (88). Much of the lipolytic response to exercise can be blocked by beta-adrenergic receptor

antagonists. Possible limiting factors to exercise while taking beta-blockers include local alterations to AT blood flow and reduction of adipose tissue and intramuscular lipolysis (89). Aerobic physical training in obese male subjects, when designed to have no effect on body weight, modifies AT lipolysis through an enhancement of beta-adrenergic responses and a concomitant blunting of adipocyte antilipolytic activity (90–92). Adrenaline- and isoproterenol-stimulated lipolytic responses *in vitro* are higher in fat cells of trained than of sedentary women, whereas  $\alpha_2$ -adrenergic responses are lower. Maximal lipolysis initiated by agents acting at the postreceptor level is also higher (93). Microdialysis studies have revealed a higher exercise-induced lipolysis in trained than in untrained subjects; beta-adrenergic response is largely responsible for this effect, since the  $\alpha_2$ -adrenergic receptor-mediated antilipolytic action is not involved in the regulation of lipolysis in subcutaneous abdominal adipose tissue of the trained subjects during exercise (94).

## V DYSREGULATION OF LIPOLYSIS IN OBESITY

As in normal-weight subjects, the distribution of body fat is subject to variation, with noticeable differences between sexes in obesity. Gender and obesity appear to influence these regional differences. Obese men have a tendency to develop central (abdominal) obesity, while a more peripheral form of obesity usually exists women. Epidemiological studies have suggested that visceral obesity has strong associations with metabolic and cardiovascular complications (73). An extended intra-abdominal fat depot appears to be the major factor contributing to increased endocrine and metabolic disorders. However, not all investigators attribute the metabolic complications of obesity to visceral adiposity (75,95). *In vitro* studies of adipocytes taken from different body fat regions suggest substantial differences in lipolysis between intra-abdominal (omental, visceral), lower-body subcutaneous, and abdominal subcutaneous regions.

*In situ* measurements of glycerol release from adipose tissue have provided further evidence that regional heterogeneity of lipolysis occurs in humans (76). In upper-body obesity, the regional variations in lipolysis between visceral and subcutaneous fat cells are more important than in normal-weight subjects. It is not clearly established whether NEFA reesterification is altered in obesity. Theoretically, primary defects might exist in adipose tissue of certain obese individuals.

Approximately 50% of newly hydrolyzed NEFA are reesterified in subcutaneous adipose tissue of weight-stable obese individuals; during weight reduction, this proportion drops to 10% (96). The true role of NEFA reesterification remains to be clarified in normal-weight, obese, and postobese, weight-stable subjects.

### A Basal Rate of Lipolysis

The basal rate of lipolysis *in vitro* is increased in enlarged fat cells of obese subjects. The differences existing in the basal rate of lipolysis *in vitro* between lean and obese subjects disappears when fat cell size is taken into account. It is known that circulating NEFA levels are increased in obese subjects and that an *in vivo* increase in the overall rate of lipolysis exists during fasting in obesity. Interpretation of results is more complex since when fat mass is taken in account, the increase is not observed (68). Microdialysis studies performed after an overnight fast in obese subjects have revealed that the lipolytic rate per tissue weight was normal in obesity (97). The mass effect due to the enlargement of body fat deposits might explain the increased overall rates of “basal” lipolysis *in vivo*, and probably explains the origin of increased plasma NEFA levels commonly found in obese subjects. The relative contribution of the various fat deposits to this increase in plasma NEFA levels represents an important factor which merit attention.

### B Differences in HSL Activity

Larger fat cells, usually found in subcutaneous deposits of obese subjects, have higher lipolysis rates, HSL activity, and HSL mRNA expression levels. Lipolysis rates correlate with fat cell size regardless of the adipose tissue region (98). Comparison of two groups of young adult nonobese subjects with or without a family trait for overweight showed that adipocyte maximal lipolytic capacity and HSL expression were lower in subjects with obese relatives (99). The data suggest a defect in fat cell lipolysis caused by an impaired expression of HSL in normal-weight subjects with a family history of obesity. Impaired lipolysis could therefore constitute an early event in the development of obesity. Moreover, a defect in HSL expression linked to an impaired lipolytic capacity in subcutaneous adipocytes was observed in massively obese subjects (100).

During a 4-week very low calorie diet, an increase in HSL expression in subcutaneous AT of obese women was reported (101). This physiological adaptation might be important to allow an intense mobilization of fatty

acids which are, during this type of calorie restriction, the preferred fuels in the body. In two independent weight reduction programs combining hypocaloric diet followed by stabilization at the new weight, the level of HSL after weight stabilization was lower than the HSL level before the program (102,103). These data show that variations in AT lipolysis and HSL expression differ between the hypocaloric and isocaloric phases of weight reduction programs. It is tempting to speculate that hereditary alterations in the regulation of fat cell lipolysis may contribute to the increase in fat mass in some subjects.

### C Catecholamine Action

It is commonly accepted that the action of catecholamines is impaired in obesity. This defect might be an early event since it has been observed in obese adolescents (104,105). A summary of the modifications of the

lipolytic responses described on human isolated fat cells in vitro or when using in situ microdialysis is given in Table 1. It is probable that this link between abnormal in vivo regulation of lipolysis and upper-body obesity is caused by regional variations of lipolysis regulation. Greater resistance to the lipolytic effect of catecholamines and the antilipolytic effect of insulin is found in subjects with abdominal than in those with peripheral obesity (71). Another important AT component, modulated by SNS activity, insulin, paracrine factors, and autacoid agents released by the adipocytes could also interfere with adipocyte function and AT physiology, which is adipose tissue blood flow (ATBF). Changes in ATBF contribute to TG clearance and facilitate the removal of NEFA and glycerol produced during lipolysis. Failure to regulate ATBF may be a feature of obesity and insulin resistance (106).

The theory on regional fat lipolysis results from a number of in vitro observations. Differences in the

**Table 1** Physiological and Pathological Modifications of the Human Lipolytic Responses to Catecholamines In Vitro in Isolated Fat Cells and In Situ Using Adipose Tissue Microdialysis

| Physiological and pathological situations     | Lipolytic response <sup>a</sup> | Modulatory effects  | Ref.    |

HSL, hormone-sensitive lipase.

<sup>a</sup> Data obtained in vitro (<sup>1</sup>) and situ (<sup>2</sup>).

lipolytic response of adipocytes to catecholamines in obese compared with lean subjects are associated with variations in the functional balance between beta- and alpha<sub>2</sub>-adrenergic receptors in AT (107,108). Reduced beta<sub>2</sub>-adrenergic lipolytic responsiveness has been reported in subcutaneous fat cells from obese subjects (109) or subjects with a reduced isoprenaline sensitivity (80). In addition, an increased antilipolytic responsiveness linked to alpha<sub>2</sub>-adrenergic receptors stimulation has also been found in subcutaneous adipocytes of obese of both sexes (107). Conversely, in visceral fat, catecholamines action is increased owing to an increased beta-adrenergic responsiveness and decreased alpha<sub>2</sub>-adrenoceptor function (110). To sum up, the lipolytic defects described in the adipose tissue of obese subjects can originate from direct HSL alterations (expression and/or function) or from multiple defects in catecholamine signal transduction pathways (beta/alpha<sub>2</sub>-adrenergic receptor balance, Gs/Gi-proteins level, and function and decreased ability of cyclic AMP and PKA to stimulate HSL).

A number of *in vivo* studies have shown blunted catecholamine-induced lipolysis in subcutaneous fat cells of obese subjects. Studies performed in adults with long-standing obesity have shown a reduced lipolytic sensitivity to catecholamines in subcutaneous abdominal adipose tissue. Unresponsiveness of the subcutaneous adipose tissue to neurally stimulated lipolysis has been described in obese subjects (111). The lipolytic defects in obese subjects have been confirmed by different groups (104,112,113). Using *in situ* microdialysis, a specific impairment in the capacity of beta<sub>2</sub>-adrenergic receptor agonists to promote lipolysis has been reported in the subcutaneous abdominal adipose tissue of obese adolescent girls (105). Moreover, when performing IV administration of selective beta<sub>1</sub>- and beta<sub>2</sub>-adrenergic receptor agonists, the increase in lipolysis and thermogenesis promoted by a selective beta<sub>2</sub>-adrenergic stimulation (salbutamol) was reduced in obese subjects. Conversely, beta<sub>1</sub>-adrenergic receptor-mediated (dobutamine) metabolic processes (*i.e.* lipolysis, thermogenesis, and lipid oxidation) were similar in obese and lean men. In conclusion, beta<sub>2</sub>-adrenergic-mediated increases in thermogenesis and lipid oxidation are impaired in the obese. It is suspected that a dysfunction of the beta<sub>2</sub>-adrenergic pathway or of the beta<sub>2</sub>-adrenergic receptor density may play a role in the etiology or maintenance of a relatively increased fat mass and, consequently, obesity. A lipolytic defect associated with a reduced NEFA availability may be the cause of an impairment of responses in energy expenditure and lipid oxidation during beta-adrenergic receptor stimulation (114).

*In vivo* studies of regional NEFA release have confirmed that adipose tissue lipolysis varies between upper- and lower-body fat. Release of NEFA from lower-body adipose tissue is less than that from upper-body adipose tissue in obese men and women (76). Although women have a higher percentage of body fat than men, there are a number of studies showing that lipolysis and the proportion of energy derived from fat during exercise is higher in women than in men (115). A recent study has demonstrated that the physiological activation of antilipolytic alpha<sub>2</sub>-adrenergic receptors could inhibit lipid mobilization in subcutaneous AT of exercising obese men. The physiological stimulation of adipocyte alpha<sub>2</sub>-adrenergic receptors during exercise-induced SNS activation contributes to the blunted lipolysis observed in subcutaneous AT of obese men (116).

However, the alpha<sub>2</sub>-adrenergic effect is weaker in the subcutaneous adipose tissue of obese women (Stich V., unpublished results). These *in vivo* results provide evidence of the contribution of fat cell alpha<sub>2</sub>-adrenergic receptors on the physiological control of lipolysis in subcutaneous AT of obese men. In hypertrophic human fat cells which express a high level of alpha<sub>2</sub>-adrenergic receptors, any reduction of the beta-adrenergic receptor-mediated lipolytic response will disturb the functional balance between alpha<sub>2</sub>- and beta-adrenergic receptor-mediated effects and amplify the reduction of the lipolytic response initiated by the physiological amines. Alpha<sub>2</sub>-adrenergic receptors in subcutaneous AT of obese subjects may have important physiopathological implications in men developing large subcutaneous fat deposits and in women with excessive hip and femoral fat deposits. Reduced AT lipolytic sensitivity to catecholamines occurring in subcutaneous AT deposits probably represent an adaptive process of the hypertrophied adipocyte. A rise in alpha<sub>2</sub>-adrenergic receptors and alpha<sub>2</sub>-adrenergic activity has beneficial effects by limiting excessive rates of lipolysis and NEFA release into the systemic circulation. Such a regulation could represent a valuable adaptative process to adjust lipolytic responsiveness to catecholamines to fat accumulation; the mechanisms leading to alpha<sub>2</sub>-adrenergic receptor overexpression are not established. It is tempting to speculate that adipocyte alpha<sub>2</sub>-adrenergic receptors may have a major contribution to the resistance of subcutaneous AT to fat loss during very low calorie diets and during physical training programs in obese subjects.

Taken together, these *in vitro* and *in vivo* findings suggest that catecholamine-induced lipolysis is decreased in subcutaneous fat but increased in visceral fat following SNS activation. This would promote a

marked increase in portal NEFA in relation to peripheral venous NEFA. Excess in portal NEFA could be a mechanism responsible for the hepatic insulin resistance usually observed in abdominal obesity. Unfortunately, a number of these speculations are based on *in vitro* studies and *in vivo* measurements of subcutaneous adipose tissue responses. For practical and ethical reasons, it is difficult to perform a direct study of portal NEFA flux *in vivo* in humans; it is the major limitation of such studies.

Moreover, in addition to catecholamines, and owing to technical limitations, the contribution of other hormones and paracrine agents exerting antilipolytic actions has not been investigated so deeply in visceral obesity. It is not clear to what extent insulin action is altered in obesity. Controversial results have been published. Insulin resistance has been demonstrated in obese subjects when insulin action is studied on glucose transport and glucose uptake by adipose tissue. Data on insulin-induced antilipolysis have shown that insulin exerts a stronger antilipolytic action in subcutaneous than in visceral fat deposits; controversies persist probably owing to the difficulties existing for the investigation of the antilipolytic actions of insulin in obese subjects. Increased, decreased or normal antilipolytic actions of insulin have been described in fat cells obtained from obese subjects (79,117). Preservation or partial or tissue-dependent reduction of antilipolytic actions of insulin could be important for the maintenance or acceleration of obesity in overweight subjects. There is a generalized resistance to insulin suppression of lipolysis in type 2 diabetes compared with equally obese nondiabetic individuals (118). Modifications of other antilipolytic mechanisms may also be involved in the adipocyte of obese subjects. Decreased antilipolytic actions of prostaglandins and adenosine have been reported in subcutaneous fat cells of obese subjects *in vitro*. These results must be interpreted cautiously since the design of *in vitro* assays for *in vivo* demonstrations do not exist for the moment. Whatever the number of *in vitro* studies on isolated adipocytes and small tissue samples, it is still difficult to extrapolate a number of *in vitro* findings to the *in vivo* situation.

## VI GENETICS OF FAT CELL LIPOLYSIS

Hereditary influences have repeatedly been reported in the control of catecholamine-induced lipolysis (101,119–121). Beta-adrenergic receptors are candidate genes for obesity because of their role in catecholamine-induced lipolysis and energy homeostasis. Polymorphisms in the  $\beta_1$ -,  $\beta_2$ -AR-, and  $\beta_3$ -adrenergic

receptors could influence adipocyte lipolysis and have an effect on the development of obesity-related metabolic disorders. Altered coupling properties of the Arg389Gly gene variant of the  $\beta_1$ -adrenergic receptor have been reported in recombinant cells. Nevertheless, distribution of the Arg389Gly polymorphism of the  $\beta_1$ -adrenergic receptor is similar in lean and obese subjects, and has no apparent effect on the lipolytic responsiveness (122). The rare  $\beta_2$ -adrenergic receptor polymorphism Thr164Ile is associated with a decreased lipolytic responsiveness of subcutaneous fat cells, suggesting that the genetic variance of the  $\beta_2$ -adrenergic receptor might be an important determinant of catecholamines responsiveness in fat cells (123). In addition, the Gln27Glu substitution in the  $\beta_2$ -AR was found twice as common in obese as in nonobese subjects in a group of women with a large variation in body fat mass.

Homozygotes for Glu27 had an average fat mass in excess of 20 kg and ~50% larger fat cells than controls (124,125). Nevertheless, change in  $\beta_2$ -AR lipolytic function was not observed. The frequency of the Glu27 is also higher in patients with type 2 diabetes, but this association could be secondary to obesity. The problem is complex and probably depends on sex-related determinants, since the positive association between obesity and the Glu27 variant in the  $\beta_2$ -AR exists in females, while, conversely, in males there is a negative correlation between the Glu27 variant and obesity (126).

The Arg16Gly polymorphism was associated with altered  $\beta_2$ -AR function with Gly16 carriers showing a fivefold increased agonist sensitivity. The frequency of Gly16 homozygotes was lower in obese than in non-obese women; women bearing the Arg16 allele had higher BMI values than Gly16Gly women. Women carriers of the Arg16Arg genotype had lower fasting plasma NEFA and greater suppression of NEFA after an oral glucose load than women bearing the Gly16 allele. Moreover, the effect of the Arg16Arg genotype on the suppression of NEFA levels was modified by physical activity level (127).

A recent population study on unselected subjects of the WHO-MONICA project in the North of France has shown that the Gly16Arg and Gln27Glu polymorphism were in strong linkage disequilibrium, as two-thirds of the women investigated carried both Gly16 and Glu27 in a hetero- or homozygous form. The study has also shown that men bearing the Gln27Gln genotype had higher body weight, body mass index, and waist-hip ratio and increased risk of obesity. If Gln27Gln men were bearing in addition the Arg16 allele, the increase in body weight and BMI, and waist-to-hip ratio was more important (128). Physical activity counterbalanced the

effect of the genetic predisposition to increase body weight, body fat, and obesity described in Gln27Gln subjects. Obese individuals with the beta<sub>2</sub>-AR Gln27Gln genotype may benefit from physical activity to reduce their weight (129). These findings suggest that polymorphisms in the coding sequence in the human beta<sub>2</sub>-AR gene could be of importance for obesity, energy expenditure, and beta<sub>2</sub>-AR-dependent lipolytic function in AT. Since some controversies still exist (130,131), deeper investigations are required before final conclusions may be reached. Determination of putative alterations of *in vitro* lipolysis and whole body lipolytic sensitivity to adrenaline is needed to complete the delineation of the various phenotypes.

Missense mutation of beta<sub>3</sub>-AR gene (Trp64Arg) has been reported to be associated with high BMI, abdominal obesity, increased capacity to gain weight, and resistance to insulin and early onset of type 2 diabetes. However, a number of controversial reports exist. Some studies did not reveal any phenotypic effect of the polymorphism. It is difficult to reach a consensus at the present time (132). The Trp64Arg polymorphism may have some influence on body weight and various metabolic parameters. However, the beta<sub>3</sub>-AR gene cannot be considered as a major obesity gene. Polymorphism-related questions become more complex when combinations of polymorphisms are considered. A recent report has shown that common variants in the beta<sub>2</sub>-(Gln27Glu)- and beta<sub>3</sub>-(Trp64Arg)-adrenergic receptor genes are associated with increased fasting insulin and NEFA concentrations, and could increase susceptibility to type II diabetes. Subjects homozygous for the protective alleles (Glu27 and Trp64) had a lower prevalence of diabetes than subjects with other phenotypes combinations (133).

The HSL gene is a candidate gene in obesity and related disorders because of its pivotal role in the control of lipid metabolism. Two highly polymorphic dinucleotide repeats have been found within introns 6 and 7. The microsatellites have been used in association and family studies within the Caucasian population. Two independent studies showed an association between the polymorphisms and obesity and type 2 diabetes (134,135). Moreover, allele 5 of the intron 6 polymorphism is associated with a marked decrease in the lipolytic rate of subcutaneous fat cells (136). Linkage analysis on families with one or more morbidly obese subject(s) was negative (137). In families with type 2 diabetes, an extended transmission disequilibrium test showed distorted transmission of alleles to abdominally obese offspring (135). The data suggest that the HSL gene may participate in the polygenic background of

obesity and/or may be a susceptibility gene important for obesity-related phenotypes.

Quantitative sib-pair linkage analysis was recently performed in dizygotic women twins to study the possible involvement of loci for lipases in changes of lipoprotein variables over 10 years (138). A linkage was demonstrated between the HSL locus and age-adjusted changes in plasma triglyceride levels, suggesting that variation at the locus may underlie a portion of the interindividual variations in this coronary heart disease risk factor. Several amino acid polymorphisms have been identified in the HSL gene. The Arg309Cys mutation found in the Japanese population is extremely rare in Caucasians (139). The more prevalent Glu620Asp and Ser681Ile have no impact on insulin sensitivity of lipolysis or glucose disposal in a lean, healthy population (140). The impact of these mutations in obese and diabetic subjects has not been investigated. A C to G change was found in the proximal adipocyte promoter and appeared to affect promoter activity (139). Women with the -60G allele may be protected against insulin resistance (141).

## VII CONCLUSIONS AND FUTURE TRENDS

The last decade has been marked by the discovery of a number of mechanisms able to clarify the control of fat storage and mobilization. Genetic variation and altered gene expression may modify HSL and adrenergic receptor function and play a noticeable role in the development of obesity. Future studies must be devoted to the delineation of the defects affecting genes encoding the various elements of the transduction pathways and the enzymes involved in the regulation of the lipolytic and antilipolytic mechanisms as well as lipogenesis. Further work will also help to understand the complex interplay between genetic and nongenetic determinants of AT function.

Altered SNS impact on its target cells could lead to the development of obesity. Reduced efficiency of beta-adrenergic receptor-dependent lipolysis and/or enhanced alpha<sub>2</sub>-AR-mediated antilipolysis could both impair lipolysis and lead to catecholamine resistance and promote the development and/or stabilization of obesity. It is the increased rate of visceral fat cell lipolysis that is commonly believed to play a pathophysiological role. The reduced lipolysis commonly reported in subcutaneous AT of obese subjects could be viewed as a physiological adaptive mechanism limiting excess rate of lipolysis. Sequestration of NEFA, in the form of TG, in hypertrophic subcutaneous fat cells may limit

deleterious metabolic actions of these metabolites. Environmental factors such as sedentary life-style may worsen a hereditary defect affecting beta-adrenergic receptor-dependent lipolysis, while physical exercise may counterbalance the influence of the hereditary defect. Much information is needed about the disturbances affecting all the steps of the lipolytic cascade and the genetic factors impacting these events. There is no doubt that studies of the interactions between genetic factors and environmental conditions will be of great interest to explain why energy storage differs so widely.

## Lipodystrophy and Lipoatrophy

**Steven R. Smith**

Pennington Biomedical Research Center, Louisiana State University, Baton Rouge, Louisiana, U.S.A.

### I INTRODUCTION

Excess adipose tissue is associated with metabolic disturbances and disease, i.e., the metabolic syndrome (1,2). Somewhat paradoxically, inadequate adipose tissue manifests itself in a similar fashion (3,4). This observation demonstrates that adipose tissue is required for normal metabolic function. The inherited and acquired lipodystrophies constitute a heterogeneous group of disorders that share the common feature of inadequate adipose tissue stores.

Although the lipodystrophic disorders represent a variety of underlying pathophysiological states, their common sequelae are instructive, as they are likely to be similar to the metabolic complications associated with “garden-variety” obesity/metabolic syndrome X. Our understanding of the pathophysiology of these patients and parallel models of lipodystrophy in animals point toward the concept of an “optimal” adipose tissue mass that matches the energy requirements of the organism. In addition, these disorders illustrate the central role of adipose tissue to (1) sequester lipid, and (2) adipose tissue as an endocrine organ.

This chapter is divided into three main sections. First, the characterized lipodystrophies and their salient features will be briefly reviewed. Second, the common pathophysiological mechanisms will be discussed in light of the available animal models. Last, based on the mechanisms by which inadequate adipose

tissue leads to disease, potential therapeutic strategies are discussed.

The following classification schema follows that of Garg (5), with reference to the schema presented by the Online Mendelian Inheritance in Man (OMIM) by McKusick (6). The reader is referred to the latter reference for a continual update of the rarer lipodystrophy syndromes and a comprehensive bibliography: <http://www.ncbi.nlm.nih.gov/Entrez/>.

### II LIPODYSTROPHIES

#### A Congenital Generalized Lipodystrophy (CGL)

CGL, OMIM 269700, i.e., Berardinelli-Seip syndrome, is an autosomal-recessive disorder that manifests at birth as a complete absence of adipose tissue, hepatomegaly, and severe nonketotic insulin resistant diabetes. Additional features include acanthosis nigricans and an elevated basal metabolic rate. Mechanical fat in the hands, feet, orbit, scalp, and periarticular fat are usually preserved (3).

#### B Familial Partial Lipodystrophy (FPL)

FPL, OMIM 151660, familial partial lipodystrophy, an autosomal-dominant disorder, is differentiated from congenital generalized lipodystrophy, an autosomal-recessive disorder, by the timing of the onset (4). FPL

manifests during or after puberty, while CGL is present from birth. The FPL syndrome occurs in both men and women, but is most apparent in women owing to the muscular appearance of the extremities and the greater amount of body fat of women in general. Patients are severely insulin resistant, have dyslipidemia with elevated triglycerides and a low HDL, and often develop overt diabetes at an early age. Three “varieties” have been described.

The *Dunnigan variety* (OMIM 151660) is characterized by loss of fat in the limbs and trunk, except for the vulva. Excess fat can accumulate in the neck, supraclavicular space, and face, and is sometimes confused with Cushing’s syndrome. Acanthosis nigricans and polycystic ovarian syndrome are uncommon. The *Köbberling variety* (OMIM 151660) is characterized by loss of subcutaneous fat in the limbs; however, the face and trunk are spared. The *mandibuloacral dysplasia variety* (OMIM 248370) demonstrates other congenital defects such as a hypoplastic mandible, severe dental crowding, persistently wide cranial sutures, and multiple Wormian bones. Acro-osteolysis is a hallmark of this syndrome.

### C Acquired Lipodystrophy

There are at least three forms of acquired lipodystrophy. *Acquired generalized lipodystrophy (AGL)* is most likely an autoimmune disease. It is characterized by a generalized progressive loss of adipose tissue, with women more commonly affected than men. Loss of fat from the soles of the feet and palms of the hands may occur. *Acquired partial lipodystrophy (APL; Barraquer-Simons)* affects the face and neck and spreads downward with sparing of the pelvic girdle and lower extremities (7). Many of these patients exhibit altered complement activation and develop glomerulonephritis with subsequent renal failure. Metabolic complications, such as insulin resistance and dyslipidemia, are uncommon. This is probably due to the sequestration of lipid in the lower extremities and the absence of increased visceral adiposity.

HIV and HIV therapy are associated with an acquired lipodystrophy (8–10). This association was recognized prior to the advent of highly active antiretroviral therapy (HAART). HIV-HAART-associated lipodystrophy was first described in individuals taking a new class of anti-HIV drugs known as the protease inhibitors, although most antiretroviral drugs have been associated with the syndrome. The first features recognized were a “buffalo hump” similar to that seen in Cushing’s disease, central-visceral obesity, and loss of fat on the extremities. More recently, the syndrome is

known to include elevated triglycerides, insulin resistance, a decrease in facial fat, particularly in the cheeks and temporal area, and loss of subcutaneous fat in the buttocks, arms, and legs. These latter changes have been described as “roping” of the superficial veins in the arms and a muscular appearance to the lower extremities.

## III SHARED PATHOPHYSIOLOGY

Several features are shared across the lipodystrophic syndromes. Several of these features are indicative of inadequate adipose tissue to sequester adipose tissue, but may also occur as a manifestation of endocrine deficits, such as hypoleptinemia, that coincide with the decreased adipose tissue mass. A hallmark of the lipodystrophic syndromes is elevated triacylglycerol levels.

At least two anatomic sites exhibit increased lipid infiltration in lipodystrophic patients—skeletal muscle and liver. The aberrant lipid storage manifests as hepatic steatosis, hepatomegaly, and an increase in skeletal muscle lipid on NMR spectroscopy. The pancreatic beta-cell has been proposed as a third site of aberrant lipid storage, but direct evidence of this in humans is lacking. These sites are also affected in patients with the metabolic syndrome X (11–13).

The insulin-resistant state associated with the lipodystrophic syndrome is frequently severe, leading to early-onset diabetes mellitus. Indeed, large doses of insulin are often ineffective at controlling blood glucose. Recent reports suggest that cardiovascular disease is accelerated, with a greater incidence in women than men (14).

### A Specific Pathophysiology/Genetics

#### 1 Familial Partial Lipodystrophy

Simultaneous mapping efforts from several laboratories resulted in the determination that the genetic defect in FPL was located at chromosome 1q21-q22. The lamin A/C gene was identified as a positional candidate, and mutations in this gene were subsequently identified in patients with FPLD in 2000 (15,16). The lamins are structural components of the nuclear pore that are thought to be involved in the trafficking of molecules between the cytoplasm and nucleus (17). Lamins A and C differ only in their differentially spliced C-terminal domains. Curiously, FPL mutations are clustered in one portion of the molecule. Mutations in other regions are associated with Emery-Dreifuss muscular dystrophy (18), limb girdle muscular dystrophy 1B (19), or autosomal-dominant dilated cardiomyopathy and conduc-

tion system disease (20). The exact mechanism(s) by which Laminin mutations result in a partial loss of adipose tissue are not known (21).

## 2 PPAR- $\gamma$ and Familial Partial Lipodystrophy

Recently, several pedigrees were described with severe insulin resistance, diabetes, and peripheral fat wasting (21a). The manifestation of this inherited partial lipodystrophy syndrome is quite similar to the metabolic syndrome X, with the exception that these patients do not respond to the antidiabetic thiazolidinediones (TZDs). These families were found to have mutations in the PPAR- $\gamma$  nuclear transcription factor gene at the ligand-binding pocket (21b). This results in impaired activation of gene transcription by the TZDs. Newer PPAR- $\gamma$  ligands with a different structural backbone may bypass this mutation in vitro. Although rare, these mutations are instructive in the sense that the metabolic sequelae are almost identical to the “garden-variety” obesity/syndrome X.

## 3 Congenital Generalized Lipodystrophy

Lamin does not appear to be involved in congenital generalized lipodystrophy, and the genetic mutation for CGL is unknown. Mapping studies demonstrate linkage to chromosome 9q34. The exact mutation has not been identified (22).

## 4 Acquired Lipodystrophy

Little is known about the immunological mechanisms that lead to the development of the acquired lipodystrophies. Many of these patients exhibit laboratory features of an autoimmune syndrome and glomerulonephritis (23).

## 5 HIV-HAART-Associated Lipodystrophy

The drugs used to treat HIV, i.e., highly active antiretroviral therapy, HAART, have themselves been associated with metabolic disturbances in individuals without HIV. However, lipodystrophy syndromes were present before HAART. As such, it is unclear at this time whether the HIV-HAART-associated lipodystrophy can be solely blamed on the pharmacotherapy. Several studies suggest that activation and rebound of the immune system during HAART are associated with lipodystrophy (8,9). In addition, almost all of the effective HIV drugs are associated with lipodystrophy. This is unusual for diverse chemical classes to manifest similar toxicities. Because of these paradoxes, it is possible that reconstitution of the immune system plays

a role in the development of HIV-HAART associated lipodystrophy.

## B Animal Models

Recent progress in our understanding of the transcriptional cascade involved in the differentiation of adipocyte precursors into mature adipocytes led to the development of transgenic models of lipodystrophy. These models came from the laboratories of Shimomura (24) and Reitman (25). The models are instructive regarding the pathophysiology of the adipose tissue deficiency and are useful in testing pharmacological interventions. A spontaneous mutation in the *lipin* gene is responsible for the *fld lipodystrophic mouse*, a novel model of the complete lipodystrophy syndrome (26,27). Detailed studies of these animal models may reveal unexpected mechanisms by which a failure to develop adipose tissue results in diabetes and metabolic derangements (28–31).

## IV THERAPY

Because of the rarity of these syndromes, little is known regarding specific therapies for lipodystrophy. There are three basic approaches based on the pathophysiology of the syndromes.

First, given that an inability to sequester lipid in adipose tissue is likely to lead to the accumulation of lipid in abnormal locations such as the liver and skeletal muscle, creating a negative fat and calorie balance is recommended. This is difficult in practice, however, and may be due to anecdotal reports of increased appetite, especially in the setting of uncontrolled diabetes. Along these same lines, the “standard” medical therapies for dyslipidemia are indicated, but for patients with hypertriglyceridemia in the face of maximal lipid and diabetes medications, plasmapheresis may be necessary. Newer therapies that target specific metabolic defects are likely to supplant this therapy.

A second approach is based on the known pathways affecting insulin sensitivity. For example, the thiazolidinediones have been used with success in the treatment of these patients (32). As a cautionary note, one of these patients developed liver complications during therapy with troglitazone, and liver enzyme testing at regular intervals may be more important than in the routine diabetic patient. Given this caveat, the newer TZDs, which are less likely to cause liver toxicity, are likely to become a first-line therapy for lipodystrophic metabolic syndromes.

A third approach is based on the observation that patients with CGL and FPL have low leptin levels. Preliminary data from the lipodystrophy groups in Dallas and Bethesda support the concept that leptin replacement is a useful therapeutic strategy. Short-term therapy with leptin resulted in a fall in triglyceride levels and a reduction in hepatomegaly in patients with lipodystrophy. This suggests that the actions of leptin to increase fat oxidation results in a decrease in tissue stores of fatty acids. This makes sense given that in vivo systems, leptin regulates fat oxidation (33,34). As more patients are enrolled in these experimental protocols and our understanding of the pathophysiology progresses, specific therapies are likely to follow these encouraging results.

## V THE FUTURE

Understanding the underlying genetic causes of the CGL syndrome is an important short-term milestone. As we understand the common mechanism by which inadequate adipose tissue stores contribute to disease, we will develop specific therapies. These therapies will consist of treatment not only for the metabolic sequelae but also for the defects in adipocyte proliferation and/or differentiation that cause these diverse syndromes. Several of these can be anticipated; i.e., drugs that increase fat oxidation, improve insulin resistance, or replace decreased hormones (e.g., leptin) are likely to occur in a shorter time span. Other therapies will not be obvious until we understand the complex mechanisms of genes such as laminin A/C or lipin and the pathophysiology of CGL.

## NOTE ADDED IN PROOF

Recent genetic studies revealed mutations in the triglyceride synthetic enzyme AGPAT2 as the cause of some, but not all, cases of CGL (35). Other cases are due to mutations in Seipin (36), also known as guanine nucleotide binding protein, gamma 3. The exact mechanism(s) responsible for the lack of adipose tissue development are still unclear (37–39).

### I INTRODUCTION

The coupling of respiration to ADP phosphorylation in mitochondria represents the coupling of exergonic and endergonic processes. Actually, such a coupling is never complete and results in energy dissipation as heat. Apart from a role in thermogenesis, uncoupling of respiration limits ATP synthesis and allows NADH reoxidation. In the absence of uncoupling mechanisms, a high level of ATP would inhibit respiration and NADH reoxidation. Two types of mechanisms have been proposed to explain the molecular basis of respiration uncoupling. The first is based on a decreased efficiency of the respiratory chain or “slippage” of respiratory chains; the second one postulates the existence of proton leaks in the mitochondrial inner membrane. Analysis of thermogenic mechanisms in brown adipocytes has established that UCP1 in the inner mitochondrial membrane works as a regulatable proton leak and an uncoupler that stimulates fatty acid oxidation (see below). The recent identification of homologues of UCP1 has extended this regulatory mechanism based on the possible mitochondrial proton leaks to virtually all other tissues. Accordingly, this phenomenon of mitochondrial proton leaks represents a widespread strategy for controlling substrate utilization, and energy partitioning through changes in metabolic efficiency.

### II UCP1

#### A UCP1 in Energy Expenditure and Body Weight Regulation

Pharmacological and genetic manipulations of experimental rodents suggest that nonshivering thermogenesis is one of the most effective strategies for reducing adiposity in obese individuals. While there are many systems of thermogenesis that are theoretically capable of increasing energy expenditure, in fact, a body of evidence confirming that a specific mechanism for increasing thermogenesis is effective in reducing adiposity is available only for mitochondrial uncoupling protein (UCPI)-dependent thermogenesis of brown adipose tissue. The previous edition of the Handbook of Obesity described the biology of brown adipose tissue, the biochemistry of UCP1, and the adrenergic signaling mechanisms that controlled the activation of nonshivering thermogenesis. Although the effectiveness of UCP1 in reducing adiposity in obese rodents is clear its relevance to obesity in humans has remained questionable because of the paucity of brown adipocytes in adult humans. Since the previous edition of the handbook was issued, important developments in mitochondrial uncoupling proteins and the regulation of brown adipocyte differ-

entiation research suggest that a review of uncoupling proteins in body weight regulation is indicated.

The prevailing paradigm guiding obesity research for the past several decades has been the thrifty metabolism ideas originally formulated by Neel (1) and subsequently developed by Coleman (2) and others in their interpretation of not only of human obesity, but also of obesity in rodent models. Briefly, modern human beings are descended from individuals who have adapted to survive during a time when caloric deprivations were common and when high levels of daily physical activity were the norm. In this environment, human evolution selected for individuals with an efficient metabolism—i.e., a maximum level of productive work per unit of food consumed. However, this efficient metabolism in the current world of plentiful food with a high caloric density and physical inactivity has resulted in an epidemic of obesity. One solution to this problem is to develop strategies that reduce metabolic efficiency. The most direct means would be to increase energy expenditure by thermogenesis, i.e., to maximize metabolic inefficiency. As noted above, uncoupling respiration from oxidative phosphorylation is an effective mechanism for heat production, but as important as the mechanism for producing heat itself is, the mechanism for the regulation of nonshivering thermogenesis is equally important. This regulation is controlled by the hypothalamus and mediated by the sympathetic nervous system. As long as adrenergic signaling mechanisms are associated with the control of expression, it is probable that the consequences of overexpression—namely, hyperthermia—will be avoided. In this section we will describe efforts to utilize heat production by the brown fat specific UCP1 for manipulating energy expenditure and adiposity.

The underlying assumption underpinning the hypothesis that UCP1-based thermogenesis could be used to reduce excess body weight, is that this mechanism of thermogenesis functions to regulate the efficiency of energy metabolism as well as to protect the animal from cold exposure. The brown fat is therefore viewed as a pathway for dissipating excess calories by thermogenesis, thereby increasing metabolic inefficiency. This view of brown fat emerged following the landmark paper of Rothwell and Stock (3), who showed that a cafeteria diet could induce nonshivering thermogenesis in rats. The implication of this finding was that in rodents, brown fat thermogenesis was not only induced by exposure to cold, but also by dietary conditions that would lead to an increased, abnormal deposition of fat. In support of this hypothesis are much data indicating that mice and rats with single gene mutations and

lesions to the hypothalamus causing hyperphagia and obesity almost invariably have reduced nonshivering thermogenesis [see review by Himms-Hagen (4)]. It suggests that in rodents a normal function of UCP1-based thermogenesis is the regulation of body weight.

However, we do not understand how this putative function of brown fat in body weight regulation is balanced and integrated with its role in regulating body temperature. Evidence that *Ucp1* expression is modulated by leptin and other orexigenic and anorexic peptides provides a biological basis for the idea that the regulation of body weight by these hormones includes the regulation of energy expenditure by UCP1. The relative balance of these functions for brown fat becomes important when attempting to extrapolate from the mouse to the human, because small body size has made brown fat much more important for the regulation of body temperature in the mouse than in the human. Does the primary and dominant role for UCP1 in maintaining body temperature in the rodent provide a secondary but important role in body weight regulation?

The possibility that agents that stimulated brown fat thermogenesis could be useful as antiobesity agents quickly led to the identification of a class of pharmacological agents that were selected on the basis of their ability to stimulate lipolysis and respiration in isolated brown adipocytes (5–7). These agonists were found to interact with atypical beta-adrenergic receptors on adipocytes (8) and were subsequently cloned and called the  $\beta_3$ -adrenergic receptor (9). While the  $\beta_3$ -adrenergic receptor agonists have proven to be effective agents to stimulate brown fat respiration, lipolysis, *Ucp1* expression, and thermogenesis and to reduce body fat in rodents and dogs (10,11), their effectiveness in treating human obesity has not been established.

There is strong evidence emerging that the discovery of mechanisms for stimulating brown adipocyte thermogenesis in a controlled manner could be an effective means for reducing adiposity. Because of the low levels of UCP1 and brown adipocytes in humans, the primary strategy will be to determine mechanisms that control both the regulation of the *Ucp1* gene and the proliferation and differentiation of the brown adipocyte in adult fat tissue. Molecular genetic approaches that have been used to explore these regulatory problems in the mouse and rat will be described below.

## **B Overexpression of *Ucp1* with Heterologous Promoters in Transgenic Mice**

Treating mice, rats, and dogs with  $\beta_3$ -adrenergic receptor agonists has increased the expression of *Ucp1*

and brown adipocytes, stimulated lipolysis, and reduced both dietary and genetic obesity (10–13). These weight-reducing effects of the  $\beta$ 3-agonists could be due to the effects of adrenergic stimulated breakdown of triglycerides in fat and subsequent oxidation of fatty acids in the muscle. However, two genetic models—one in which *Ucp1* was constitutively expressed in both white and brown fat from the aP2 gene promoter (14), and the other in which *Ucp1* was expressed in muscle from the myosin light chain promoter (MLC-*Ucp1*)—both gave very similar phenotypes (15). The aP2-*Ucp1* transgenic mice were resistant to both genetic and dietary obesity (14,16), and the MLC-*Ucp1* transgenic mice were resistant to dietary obesity, and both transgenes reduced the hyperglycemia and insulin resistance that develops in the background strains used when fed a high-fat diet.

Transgenic systems for overexpression of *Ucp1* have underscored the effectiveness of UCP1-mediated uncoupling on reduction of adipose stores and increasing insulin sensitivity. Since the levels of UCP1 in white fat and the level of UCP1 in muscle in transgenic mice hemizygous for the transgenes were both  $\sim 1\%$  of normal brown fat levels, it indicates that very small increases in uncoupling-based thermogenesis are effective in reducing adiposity (15). They also show that it is not necessary to have expression of UCP1 in brown fat or even in white fat to be effective. However, the experiments also illustrate how important it is to control the limits of overexpression. Transgenic mice homozygous for the aP2-*Ucp1* transgene lose  $\sim 95\%$  of their brown adipocytes owing to cytotoxicity of UCP1 at excessive levels in brown adipocytes (17), and mice homozygous for the low-expressing MLC-*Ucp1* transgenic animal have severely reduced body weights (15). Since the levels of muscle phosphocreatine and ATP were 60% of normal in mice homozygous for the MLC-*Ucp1* transgene, it suggests that excessive uncoupling by UCP1 is lethal to the cell. The inability of the muscle to maintain ATP levels in the face of excessive uncoupling suggests that normal mechanisms of controlling proton flux at the membrane level are not sufficiently effective in preventing excessive uncoupling (18). Although the transgenic mice were not hyperthermic, it is clear that controlling the level of UCP1 is very important if one is to avoid serious side effects. One problem with an approach to overexpression that is modeled after the transgenic mice described above, is that unlike the normal endogenous *Ucp1* gene, which is stringently regulated by the adrenergic nervous system, the aP2 and MLC promoters are constitutive promoters that are not known to modulate expression through the action of effectors, hormones, etc. Thus, any approach to

upregulating the *Ucp1* gene must occur where tight regulatory control is maintained, optimally its own adrenergic signaling system. The value of these transgenic animals is that they have established the principle that upregulation of UCP1 can reduce both obesity and insulin resistance.

### C Natural Variation in the Expression of Brown Adipocytes in White Fat Depots

An alternative approach to increasing *Ucp1* gene expression is based on increasing the number of brown adipocytes in an individual. This approach directly addresses the problem of limiting numbers of brown adipocytes in adult humans that preclude a robust response to an adrenergic agonist. It has been observed among several mammalian species that chronic sympathetic stimulation by either cold exposure or adrenergic agonists leads to an increase in brown adipocytes in traditional white fat depots as evidenced by increases in the *Ucp1* expression or by the histological appearance of adipocytes with a multilocular morphology (10,11,19,20). This inductive response may also occur in humans. For example, Finnish laborers working outdoors in the winter months are reported to have larger deposits of brown adipocytes (21), and patients carrying catecholamine-secreting pheochromocytoma develop large depots of brown fat (22). The former report suggests that the increase in brown adipocytes enhances the thermogenic capacity of the laborers; the latter report underscores the possibility that humans have the capacity to increase the number of brown adipocytes.

There is evidence that increased numbers of brown adipocytes in rats treated with  $\beta$ 3-adrenergic agonists reduce obesity caused by either a mutation to the leptin receptor or a high-fat diet (11,13). Rats treated with the drugs lost weight and also had elevated numbers of brown adipocytes. However, it is not clear whether rats with induced levels of brown adipocytes lost weight because of increased energy expenditure derived from increased numbers of brown adipocytes or weight was lost by some other mechanism. Similarly, when inbred strains of mice that varied in the numbers of brown adipocytes were treated with a  $\beta$ 3-agonist, those strains with more brown adipocytes lost more adipose tissue (23). The same caveat holds for this experiment, since it is possible that other biochemical differences, rather than brown adipocyte number among the strains, affected adiposity.

There has been a careful quantification of *UCP1* expression in human adipose tissue from lean and obese individuals by quantitative RTPCR (24). In this study,

it was estimated that approximately one of every one to two hundred adipocytes in human fat depots is a brown adipocyte (24). This is quite a significant level of expression given the fact that expression of a *Ucp1* transgene in mouse muscle at only 1% the level detected in brown fat is able to reduce adiposity and insulin resistance (15). The data of Oberkofler et al. (24) also suggested that *Ucp1* mRNA levels were reduced in the fat depots of the obese individuals, and those researchers speculated that this reduction could reduce energy expenditure in these individuals. Further work needs to be done in both nontransgenic obese animal models and obese humans to establish whether variation in *Ucp1* expression in white adipose tissue can contribute to the level of adiposity.

With the finding that the induction of brown adipocytes in white fat depots varied among inbred strains of mice (23,25), an effort is under way to identify novel cell signaling and transcriptional pathways that can be used to induce brown adipocyte numbers in traditional white fat depots. The objective is to use quantitative genetic methods to map and clone genes that control brown adipocyte differentiation. Quantitative trait locus (QTL) analysis has defined regions on chromosomes 2, 3, 8, and 19 that control brown fat induction in mice (26). Only the QTL on chromosome 8 carries a known gene that could be involved in UCP1 expression and that gene is *Ucp1* itself. However, the genetic data cannot define with sufficient precision the location of the variant genes to any of the QTLs, including those on chromosome 8, to ascribe confidently to them a function in *Ucp1* induction. Since the QTLs on chromosomes 2, 3, and 19 do not carry genes known to be associated with either *Ucp1* expression or adipogenesis, it is highly probable that novel rate-controlling steps in the signaling or transcription of *Ucp1* expression will be discovered from these genetic studies. The evidence that complex interactions between chromosomes 8 and 19 are involved in the regulation of *Ucp1* induction suggests that epistatic gene interactions are controlling *Ucp1* expression.

These genetic studies on brown adipocyte induction are still at early stages. In addition, they have only addressed the regulation of *Ucp1* expression and have not yet investigated the regulation of mitochondrial biogenesis nor other aspects of brown adipocyte differentiation. While *Ucp1* expression and mitochondrial biogenesis will likely share some regulatory mechanisms, such as the known involvement of PGC1 in both, we expect that there will be mechanisms that are unique for each process. Considering that the brown adipocyte in the human is similar to that in other species in its

dependence on adrenergic signalling, it is quite possible that the pathways that control variation in the expression of brown adipocytes in the mouse will also exist in the human. The genetic dissection of the regulation of brown fat induction in mice will hopefully identify the details of the inductive pathways and provide alternatives sites for pharmacological intervention.

#### **D Variation in *Ucp1* Expression in Transgenic and Knockout Models**

Transgenic mice have the potential to provide insight into the regulation of brown adipocyte expression. To date, the major phenotype is one in which hypertrophy of interscapular brown fat occurs because of the effects of the transgene on energy expenditure and thermogenesis. Overexpression of the cytoplasmic glycerol-3-phosphate dehydrogenase induces thermogenesis systemically, possibly by a substrate cycling mechanism, with the consequence that a large increase of the lipid droplets occurs in the brown adipocytes because of reduced lipolysis and thermogenesis as evidenced by reduced *Ucp1* expression and elevated leptin (27). Inactivation of the hormone-sensitive lipase gene causes a similar hypertrophy because of the reduced capacity of the tissue to utilize its lipid stores (28). A dramatic increase in brown fat due to accumulation of lipid occurs in mice carrying the sterol regulatory element-binding protein (29). These mice have virtually undetected levels of *Ucp1* mRNA, in brown fat, which is peculiar since the levels of leptin mRNA are also very low. Normally, if brown fat is inactive owing to reduced sympathetic input, leptin expression is increased. The phenotype of this mouse in which brown fat is enlarged, white fat is shrunk, and both leptin and *Ucp1* expressions are reduced suggests that overexpression of SREBP-1 by the aP2 promoter has caused a major disruption of the adipocyte differentiation program.

An important mechanism for both enhancing the expression of *Ucp1* in the brown fat and stimulating the conversion of brown adipocytes in white fat depots has emerged from two disparate studies. In one study, the targeted gene inactivation of the RII $\beta$  regulatory subunit of protein kinase A resulted in animals that showed striking reductions in adiposity, especially in mice fed a high-fat diet (30). These animals had elevated levels of UCP1 in brown fat owing to an increase in protein kinase A activity that occurred when the inactivation RII $\beta$  subunit gene was compensated by an increase in the levels of the RI $\alpha$  regulatory subunit. In mutant mice, the holoenzyme of protein kinase A with the RI $\alpha$

subunit binds cAMP with higher avidity than in wild-type mice, thereby lowering its threshold for activation and subsequent stimulation of CREB-mediated transcription. In a second study, a winged helix/forkhead transcription factor FOXC2 was overexpressed in adipose tissue of transgenic mice with the  $\alpha$ P2 promoter (31). Similar to the RII $\beta$  regulatory subunit targeted mice, the FOXC2 transgenic mice had increased expression of *Ucp1* in brown adipose tissue and, in addition, had an increase in the expression of the brown adipocytes in white fat depots. The increase in PGC1, PPAR $\gamma$ , and ADD1/SREBP in the white fat depots of transgenic mice suggests that the overexpression of FOXC2 stimulates the brown adipocyte differentiation program in the white fat depots. The mechanism by which FOXC2 induces these changes appears to be mediated by changes in the expression of the regulatory subunits of protein kinase A. FOXC2 preferentially stimulates the expression of the RI $\alpha$  regulatory subunit, thereby establishing a cAMP system with heightened activity. The results with FOXC2 show how the induction of both *Ucp1* expression and the brown adipocyte differentiation are exquisitely sensitive to cAMP signaling. Consistent with these models is an earlier transgenic model in which the  $\beta$ 1-adrenergic receptor was overexpressed from the  $\alpha$ P2 promoter and resulted in an increase in brown adipocyte expression (32). However, in a follow-up analysis of the effects of the RII $\beta$  subunit gene inactivation on gene expression associated with lipolysis and gene expression in white fat depots, those effects that would indicate a striking increase in brown adipocyte expression in the white fat of the knockout mice were much more modest (33). Whether the differences between the RII $\beta$  knockout and FOXC2 overexpression systems are due to background strain effects, sex, or type of fat pads analyzed need to be resolved.

In summary, alternative strategies are being discovered by which an enhancement of cAMP signalling can activate the brown adipocyte differentiation program in white fat as follows: 1.) The FOXC2 transgenic model has revealed a novel mechanism by which sensitivity of PKA signalling can be modulated by regulating expression of the PKA regulatory subunits; 2.) the genetic analysis of brown fat induction in mice has identified at least four more chromosomal regions in which reside novel genes that can also stimulate *Ucp1* expression. Accordingly, it is possible that additional strategies for upregulating brown adipocyte differentiation will be discovered. The fact that FOXC2 is abundantly expressed in human adipose tissue suggests that the machinery for inducing brown fat expression also exists in the human (31).

## E UCP1 and Hormones of Feeding Behavior

Shortly after the discovery of ob/ob mice, Alonso and Maren (34) demonstrated that the total body weight of ob/ob mice pair-fed with nonmutant littermates was similar to that of controls, but the percent body fat was still similar to that of ob/ob mice fed ad libitum. Several years later, in a repeat of this experiment that included db/db mutant mice, Coleman noted that hyperphagia, although a major contributory factor to the amount of fat accretion, was not essential for the development of either obesity or diabetes (35). Rather, he concluded, the *ob* and *db* genes have major effects on the partitioning of calories. With the cloning of the *ob* gene, the effects of leptin on body composition, presumably through its action on energy expenditure, was confirmed when ob/ob mice treated with leptin showed normalized food intake and total body weight as well as a normal body composition (36). Several laboratories have now demonstrated that in addition to the effects of leptin on food intake, it also increases energy expenditure by stimulating *Ucp1* expression in brown fat via the sympathetic nervous system (37–40). The ability of neuropeptides of food intake to have peripheral effects on energy expenditure is not restricted to leptin, but is a property shared by other anorexic agents, including the melanocortin system.

Similar to leptin action, the melanocortin system for the regulation of food intake and body weight is a system of agonists ( $\alpha$ -MSH) and antagonists (agouti-related protein and agouti protein) acting on the MC3R and MC4R receptors. Inactivation of the receptors by gene targeting or treatment with antagonists causes increases in food intake and the development of obesity in a manner resembling mutations to leptin or the leptin receptor (41,42). In fact, the pathway for action of leptin signaling in the hypothalamus appears to be partially mediated by MC3R and MC4R (43,44). Although the evidence is not as clear as in the experiments with ob/ob mice, mice with mutated MC3R or MC4R genes or mice treated with an antagonist have an increase in adiposity even when pair-fed to control/untreated animals (45).

An important finding in these studies is that *Ucp1* expression is upregulated when energy expenditure is increased and downregulated when energy expenditure is reduced. The emerging conclusion is that leptin and  $\alpha$ -MSH inhibition of food intake stimulates sympathetic nervous activity to brown adipose tissue to induce *Ucp1* expression, while AGRP and NPY stimulate food intake and attenuated expression of *Ucp1* (46,47). The implication of these phenotypes is that UCP1 plays a

role in determining changes in peripheral energy expenditure initiated by the action of leptin. Given that even UCP1-deficient mice are not obese (48), the relative contributions that changes in *Ucp1* expression may have in modulating energy expenditure and adiposity by anorexic and orexigenic peptides remains uncertain. Even more uncertain is the contribution that this mechanism has in modulating energy expenditure in humans.

## F Regulation of the Endogenous *Ucp1* Gene

*Ucp1* is activated in response to growth and development, environmental temperature, and nutrition status. Much of this regulation is coordinated centrally from the hypothalamus via the sympathetic nervous system; however, other aspects of regulation appear to proceed independent of the sympathetic nervous system, and some regulation may require both the SNS and mechanisms independent of the SNS. In parallel with these expression studies, several research groups have been characterizing the regulatory motifs, located in the 5' flanking region of the gene, and identifying the transcription factors that interact with these motifs. The picture emerging from these studies is that a number of motifs and factors have been identified that may interact in various combinations to regulate *Ucp1* transcription under a specific set of conditions. What these combinations may be for a given function remains to be determined.

The general structure of the 5' regulatory region of *Ucp1*, depicted in Figure 1, highlights two major domains—the proximal promoter, and a distal enhancer region. These regions are highlighted because expression studies based on transgenic mice and transient expression assays in cultured cells of the regulatory motifs from the mouse and rat genes have shown consistent results. Other motifs, principally those located between the proximal promoter and the distal enhancer, have been identified by comparative sequence analysis, but have not been clearly verified by expression studies. In addition, there is evidence for a silencer located ~1 kb from the transcription start site, but the identity of the sequences specifying this function has not been determined. Finally, strong DNase hypersensitive regions 16 kb upstream of the transcription start site of *Ucp1* have been mapped. Whether these sites are the location of *Ucp1* regulatory motifs, such as a distal locus-controlling element, is not known.

An absolute requirement for a CRE in the proximal promoter has been shown by site-direct mutagenesis of the CRE in both the mouse and the rat gene (49,50). It is probable that cJun is involved in regulation from this

**Figure 1** Schematic representation of the 5' flanking regulatory region of the *Ucp1* gene. Known transcription factors and effectors are listed. The nucleotide positions of the enhancers and proximal promoter regions are those that have been determined for the mouse gene, but the mouse and human genes have comparable locations for these regulatory elements. The overall size and relationship of transmembrane domains to exon/intron structure is also similar among the rat, mouse, and human (173–175). Additional elements are likely to reside between the proximal promoter and distal enhancer, but these have not been well characterized at this time.

site, but it is not determining the differentiation-dependent expression of *Ucp1* (50). Whether the proximal CRE is required for retinoic acid-dependent induction of gene expression is not known. Sp1 and NF1 motifs have been identified by sequence analysis; however, there is no other evidence that these motifs have a function in the promoter (51).

The distal enhancer region is extremely complex with evidence for the involvement of 10 or more transcription factors (Fig. 1). The importance of this region was first identified in transgenic mice (52) and subsequently by deletion and mutation analysis in transient expression assays in brown adipocyte cultures (49,53). PPARE region in the distal enhancer was rigorously characterized as the PPAR $\gamma$ -binding site by Sears et al. (54), thereby providing the groundwork that led to the discovery of PGC1 as a coactivator of PPAR $\gamma$  together with RXR $\alpha$  (55). Corroboration of

the importance of the PPRE site and its interaction with PPAR $\gamma$  and RXR $\alpha$  and its role in *Ucp1* regulation has also established by analysis of the rat *Ucp1* gene (56). Importantly, not only PPAR $\gamma$ , but also PPAR $\alpha$ , has a role in the regulation of *Ucp1* (56). A second site in the distal enhancer contains motifs for regulation by retinoic acid and thyroid hormone (57–59). Mutation analysis in both the mouse and rat genes has also identified an ETS binding domain located between the PPRE/CRE region and the more proximal RARE/TRE domain (49,51).

The human *UCP1* gene also has a multipartite element in an upstream enhancer (located between -3.82 and -3.47 kb from the transcription start site) that mediates its expression. As determined in mouse cells by transient expression analysis, maximal expression depends on simultaneous addition of retinoic acid, isoproterenol and thiazolidinediones (60). Very little expression could be detected with addition of only one of these effectors independently, and only low expression was detected when one of the three effectors was absent. The requirement for thiazolidinediones occurred even though a consensus PPRE motif could not be detected. These results suggest that upregulation of the human *UCP1* will depend on transcription mechanisms similar to those that control the rodent gene.

Why does there seem to be so much redundancy built into the regulatory mechanisms? Does regulation of the *Ucp1* require all of these transcription factors all the time, or are there physiological conditions when only a subset of factors is required? It has been proposed by Villarroya and colleagues that retinoic acid, which has been shown to induce *Ucp1* expression, as well as norepinephrine, albeit with a delayed time course (57,59), could be the primary transcription mechanism controlling *Ucp1* expression during in utero development between 18 and 19 days (61). This mechanism assumes that in utero *Ucp1* is not capable of being stimulated by adrenergic signaling. Given that dopamine  $\beta$ -hydroxylase-deficient mice die in utero and that  $\beta$ -adrenergic signaling stimulates brown adipocyte proliferation and differentiation (62,63) in tissue culture, further experimentation needs to be performed to understand the effects of adrenergic signalling on *Ucp1* expression in utero. The discovery by Villarroya and colleagues that *Ucp1* is regulated by effectors of PPAR $\alpha$  as well as PPAR $\gamma$  (56) suggests that while PPAR $\gamma$  is required for expression of *Ucp1* during BAT differentiation, PPAR $\alpha$  upregulates *Ucp1* during active thermogenesis when PPAR $\alpha$  also controls the expression of genes encoding enzymes for fatty acid oxidation.

## G Genetic Variants in UCP1 and Susceptibility to Obesity

Whether genetic variation in *UCP1* expression could increase susceptibility to obesity in humans is a question that is still unresolved. Genetic studies evaluating this issue are inconclusive, since some studies have reported significant associations between *UCP1* polymorphisms and body weight (64–66) while others have not (67–69). Without knowledge of some functional change associated with a given polymorphism, it is difficult to interpret these association and linkage data, and there is little information on UCP1 function. Oberkofler et al. (24) found lower *UCP1* mRNA levels in the intraperitoneal fat depots, but not extraperitoneal fat depots, of morbidly obese subjects compared to lean controls. Whether this difference is indicative of lower energy expenditure in the obese individuals and is causally linked to the development of obesity is unknown.

## H Perspectives on UCP1

Even a small increase in the expression of *Ucp1* has been shown to have strong effects in reducing the development of obesity and type 2 diabetes in rodent models. Much of this information has come from transgenic and gene knockout models. However, these genetic models have not only established that stimulation of UCP1 is effective as an antiobesity target, but they have also revealed novel signalling and transcription pathways that will promote the emergence of differentiated brown adipocytes in white fat tissues. As this manuscript goes to press, two studies have elegantly shown this, one on the effects of overexpression of FOXC2, a transcription factor (31), and the other on the targeted inactivation of 4E-BP1, an inhibitor of translation (70). Both mechanisms for the control of gene expression result in the same phenotype, that is, increases in brown adipocytes in traditional white fat depots and concomitant reductions in adiposity. The emergence of a multitude of targets for unregulating *Ucp1* in the mouse provides much hope that some of these will become effective targets for the unregulation of *UCP1* and brown adipocyte-derived thermogenesis in human.

## III THE NOVEL UCPS

Brown fat mitochondria are characterized by an active proton pathway that can be uncoupled by an adrenergic stimulation by activation of UCP1. Data from several studies finding that the coupling of respiration

to ATP synthesis in mitochondria from several tissues was less than perfect and also due to proton leaks (71). With the identification of UCP2 and UCP3, two homologs of the brown fat UCP in 1997, the hypothesis emerged that mitochondrial proton leaks in skeletal muscle or in liver or brain mitochondria were due to proteins homologous to brown fat UCP. UCP2 is widely expressed in tissues, whereas UCP3 is mainly expressed in skeletal muscle and brown adipose tissue. The high level of identity among UCP2, UCP3, and UCP1, as well as preliminary functional, physiological, and genetic studies (72–77), supported a putative role for these novel UCPs in energy expenditure and metabolic regulation. However, subsequent studies, in particular the observation that UCP2 and UCP3 gene expression was induced in skeletal muscles in humans (78) or rodents (79) during starvation and that UCP2 was present in ectothermic vertebrates (80), questioned the role for the novel UCPs in energy expenditure. In this chapter, we will not discuss the roles of other mitochondrial carriers identified in mammals, plants, or birds that are more or less related to the UCPs and are referred to as BMCP1 (81), UCP4 (82), plant UCP (83), and avian UCP (84,85). This section of the review on UCP2 and UCP3 will present data from biochemical, genetic, physiological, and pathophysiological studies in human and rodent models as well as data from the analysis of transgenic mice.

## A Biochemical Studies

The questions to address are: Are the novel UCPs true uncouplers of respiration? Do they work as proton translocators? Are they regulated by fatty acids or nucleotides? Do they affect ATP level in cells?

Expression of UCP1 in yeast or reconstitution studies of UCP1 into liposomes was previously used to demonstrate its ability to uncouple respiration and translocate protons. In these systems, UCP1 uncoupling activity is increased by addition of fatty acids and is decreased in presence of nucleotides, as it is in brown adipocyte mitochondria (86–88). Similarly, expression of human or rodent UCP2 or UCP3 in yeast induces a marked uncoupling of respiration and thermogenesis (73,74,89–92). In addition, liposomes reconstituted with UCP2 or UCP3 purified from recombinant bacteria were able to catalyze an electrophoretic flux of protons (93). Using a similar approach, Echtay et al. also observed a proton transport activity in lipidic vesicles reconstituted with UCP2 or UCP3 (94). However, the physiological significance of uncoupling activity of UCP2 or UCP3 in recombinant yeast was recently

criticized by Brand and colleagues who reported that physiological levels of UCP2 were unable to significantly uncouple respiration of yeast mitochondria (95). These authors claimed that the observed uncoupling of respiration might be due to damaged mitochondria from the large excess of recombinant proteins. They also draw attention to the fact that the increase of UCP3 mRNA in the skeletal muscle of starved rats was not accompanied by a change of proton conductance (96). A problem with interpretation of many of the reconstituted systems, whether from yeast or liposomes, has been the lack of careful quantification of the protein in these preparations.

In isolated yeast mitochondria, unlike UCP1, UCP2, or UCP3, activity is regulated by neither fatty acids nor nucleotides (91,92). However, a direct activation of UCP2 by retinoids was observed in yeast mitochondria (92). This effect of retinoids on UCP2 was confirmed in a reconstitution system (97). In contrast to studies in yeast, the reconstituted proton transport activity of UCP2 or UCP3 in liposomes has an obligatory requirement for fatty acids (94,98). Proton flux was also inhibited by nucleotides in liposomes, but with much lower affinity than observed with UCP1 (98). Klingenberg and coworkers have recently reported on the striking effects of coenzyme Q as an obligatory cofactor for the  $H^+$  transport in liposomes reconstituted with UCP1, UCP2, and UCP3 (99). They also proposed that these  $H^+$  transport activities conducted in the presence of coenzyme Q are regulated by the concentration of free ATP and ADP and by the ATP/ADP ratio (94).

The biochemical functions of UCP2 and UCP3 have been explored by overexpression of the proteins in mammalian cells and transgenic mice, and by inactivation of their genes in mice targeted by homologous recombination (the data referring to transgenic mice are reviewed below). Overexpression of UCP2 in rat pancreatic islets (100,101) or insulinoma cells (102) resulted in a severe blunting of glucose-stimulated insulin secretion and significantly reduced ATP content (101,102) and mitochondrial membrane potential (101). Consistent with these effects of overexpression, UCP2-deficient mice had higher islet ATP levels and increase of glucose-stimulated insulin secretion. These studies support a true uncoupling activity of UCP2 and a negative role for UCP2 in the control of insulin secretion. The presence of UCP2 in pancreas (73,74, 101,103–105) and the well-known control of insulin secretion by ATP/ADP ratios in  $\beta$ -cells also support their findings from these genetic studies. Overexpression of human UCP3 in L6 myotubes or H9C2 cardiomyoblasts stimulates glucose uptake and GLUT4

translocation to the cell surface by activating a PI3K-dependent pathway (106). Such an effect could be related to uncoupling activity of UCP3 and a subsequent requirement for substrate utilization. Another study of overexpression of human UCP3 in cultured human muscle was shown to favor fatty acid over glucose oxidation (107).

In summary, it is obvious that unphysiological levels of UCP2 or UCP3 can uncouple respiration in yeast or mammalian cell and translocate protons through a membrane, but it is not certain whether the low physiological levels of these proteins may be sufficient to induce a net uncoupling of respiration in vivo. The divergent observations of the regulation of the activities of UCP2 or UCP3 by fatty acids or nucleotides will require further studies. Interestingly, Moore et al. recently proposed that UCP2 and UCP3 could export fatty acid anion under conditions of elevated fatty acid oxidation (108). Expression studies of UCP2 in pancreatic cells agree with an uncoupling activity, but the demonstration that a concomitant decrease of ATP content directly results from respiration uncoupling should be further confirmed. Another important role for UCP2 and UCP3 may be related to the control of reactive oxygen species (this point is discussed in the section on transgenic mice).

## B Genetic Studies

The *UCP2* and *UCP3* genes are adjacent genes on human chromosome 11 and mouse chromosome 7 (109–112). Sequence analysis has shown a similar distribution of the coding domain over six exons and a similar localization of exon/intron boundaries, which suggests that *UCP2* and *UCP3* have evolved by duplication from a common ancestor, as their juxtaposition on the chromosome predicts (109,112–116). In comparison with the *UCP1* gene, the *UCP2* gene contains two additional exons in the 5' side, whereas the *UCP3* gene contains one additional untranslated exon in the 5' side. Exon 1 of *UCP2* is untranslated and exon 2 contains an open reading frame of an unknown 36-amino acid peptide (112). Actually, exon 2-ORF seems to limit *UCP2* synthesis and may be important for the translational regulation of the *UCP2* gene (117). In contrast to *UCP3* promoter (116), the *UCP2* promoter lacks both TATA and CAAT boxes and is GC rich (112,115). Promoter studies have identified a positive regulatory region in the proximal part of *UCP2* and *UCP3* promoters (112,114,116), and a double E-box mediating PPAR $\gamma$  response in *UCP2* promoter (118). The *UCP3* promoter contains several MyoD-binding motifs (119),

and its activity in vitro is largely dependent on MyoD (120).

The genetic linkage of the *Ucp2* locus to hyperinsulinemia in mouse (73) and the putative respiration uncoupling activity of the novel *UCPs* stimulated geneticists to investigate the contribution of these genes to metabolic physiology and pathophysiology in humans. The first genetic analysis in the human revealed a significant linkage of an anonymous marker, D11S911, lying close to the *UCP2* and *UCP3* genes, to resting metabolic rate in Caucasians (77). This first study hinted at a potential role of the novel *UCPs* in energy expenditure. A genomic scan for genes affecting body composition before and after exercise training in Caucasians identified the *UCP2/UCP3* locus as a region linked to change in percent fat (121). However, another study failed to find significant linkage between the *UCP2/UCP3* region and obesity in familial type 2 diabetes (122). In another analysis, the D11S911 marker in the *UCP2/UCP3* gene cluster was associated with anorexia nervosa in a cohort of 170 female Caucasians (123).

Two common polymorphisms were identified in human *UCP2* gene: one nucleotide substitution at codon 55 in exon 5 replacing an alanine with a valine (124–126), and a 45-bp insertion/deletion variant in the untranslated region of exon 8 (127). A rare variant resulting in an alanine/threonine substitution at position 232 was also described (128). The alanine/valine substitution polymorphism was related to metabolic efficiency, fat oxidation, and energy cost of physical exercise in a Danish population (129,130). However, this alanine/valine polymorphism was not associated with the pathogenesis of juvenile or maturity-onset obesity or insulin resistance in Caucasians (124,131) or with basal metabolic rate and susceptibility to obesity in Caucasians or Japanese (126,128). The 45-bp insertion/deletion polymorphism in exon 8 is associated with body mass index in South Indian subjects but not in obese Caucasians (132) or in morbidly diabetic obese French subjects (131). Confirming a genomic scan analysis, the insertion/deletion polymorphism in the 3' untranslated region of exon 8 was calculated to be associated with gain in fat mass over 12 years, suggesting that *UCP2* might be associated with an increased susceptibility to gain fat with age (121). Yanovski et al. reported that this polymorphism was associated with body mass index in childhood-onset obesity (133). An association with obesity was also observed in German adults (134).

More recently, another common variant in the promoter region of human *UCP2* was described (G/A at position bp -866 relative to the transcriptional start site); this variant is associated with decreased risk of

obesity in middle-aged humans in a cohort of 790 individuals (135).

The different variants identified in the human *UCP3* gene are the following: four nucleotide substitutions in the intron 3, and two silent amino acids (Tyr/Tyr at position 99 in exon 3, Tyr/tyr at position 200 in exon 5); substitution of a glycine residue for a serine residue at position 84 of amino acids in exon 3 (113); substitution of a valine for an isoleucine at position 102 in exon 3; a mutation introducing a stop codon in exon 4 (arginine residue at position 143); a terminal polymorphism in the splice donor junction of exon 6, resulting in a short form of UCP3 protein lacking the N-terminal transmembrane helix (136); substitution of a valine for a methionine at position 9 in exon 2; and substitution of an arginine for a tryptophan at position 308 in exon 7 (137). It is unlikely that variants in exons 3 and 4 of the *UCP3* gene contribute to the pathogenesis of juvenile-onset obesity among Danish Caucasians (113) or obesity in French (137) or Isle of Ely Caucasians (138). In contrast with these studies, Argyropoulos et al. (136) observed that the exon 6–splice donor polymorphism correlated significantly with basal fat oxidation and respiratory quotient in morbidly diabetic obese Gullah-speaking African-Americans (but not in Caucasians). They proposed a role for UCP3 in metabolic fuel partitioning. However, these data were not confirmed in an independent population of African-Americans (139). In other respects, a GA polymorphic site in intron 6 of *UCP3* gene was calculated to be strongly associated with body mass index and body fat content in the Quebec family study (140). C-to-T substitution in the *UCP3* promoter, 55 bp upstream of the transcriptional start site, has been detected; this polymorphism is associated with *UCP3* mRNA levels (141,142). The C-to-T polymorphism in the 5' sequence of the *UCP3* gene is negatively associated to body mass index (138,143). Interestingly, in the group with the C/C genotype, body mass index was negatively associated with physical activity, suggesting that the *UCP3* gene might contribute to corpulence and alter the benefit of physical activity (143). Therefore, although the *UCP2* and *UCP3* genes are not major genes for human obesity or metabolic diseases, several studies identified the *UCP2/UCP3* locus as a region possibly implicated in the control of resting metabolic rate, fat oxidation, and adiposity in humans.

### C Physiological and Pathophysiological Studies

Several studies have aimed at understanding the physiological significance and regulation of UCP2 and

UCP3. These studies were related to (1) effects of hormones, substrates or drugs on UCP expression, (2) status of UCPs in obese or diabetic patients, and (3) the relationship between UCP2 and UCP3 and physical exercise.

The identification of UCP homologs able to uncouple respiration in recombinant systems prompted the authors to propose that such proteins were involved in basal or regulatory thermogenesis. In agreement with this hypothesis, Barbe et al. reported that the level of *UCP2* mRNA in adipose tissue of obese humans after 25 days of hypocaloric diet correlated with resting metabolic rate adjusted for lean body mass (144). The hypothesis that the UCP homologs could stimulate thermogenesis is supported by several studies showing that they were upregulated by thyroid hormones in rodents (76,145,146). The effect of thyroid hormones was tested in humans receiving an amount of T<sub>3</sub> causing a 1.7-fold increase in plasma-free T<sub>3</sub> level, a 14% increase in resting metabolic rate, a small decrease in respiratory quotient, and no change in plasma level of nonesterified fatty acids (147). In this study, T<sub>3</sub> increased *UCP2* mRNA levels in adipose tissue as well as *UCP2* and *UCP3* mRNA levels in skeletal muscle. In addition, the direct effect of T<sub>3</sub> on skeletal muscle and adipose tissue *UCP2* and *UCP3* mRNA was demonstrated in vitro with human primary cultures. A marked upregulation of *UCP2* mRNA was also described in adipose tissue of hyperthyroid patients (148).

Soon after the discovery of *UCP2* and *UCP3*, an upregulation of *UCP2* and *UCP3* mRNAs upon starvation was described both in humans (78) and rodents (79,149). Such data questioned the hypothetical role for the novel UCPs in energy expenditure in the face of depleted energy reserves; however, it was suggested that the UCPs could provide for the important function of maintaining body temperature that could occur during starvation. Dulloo and Samec have proposed that the function of *UCP2* and *UCP3* was rather to adapt cell metabolism to lipid utilization rather than thermogenesis (149). In agreement with this proposal, the upregulation of *UCP2* and *UCP3* mRNAs by a high-fat diet in humans is more pronounced in humans with high proportions of type IIA fibers, which are known to have a high capacity to shift from carbohydrate to fat oxidation (150).

To explain *Ucp3* induction in skeletal muscle during food restriction of rats, Weigle et al. proposed that the free fatty acids are the mediators of such a change (151). In agreement with this work, infusion of lipids for 5 hr in human volunteers induces a rise in nonesterified fatty acids and a doubling of *UCP3* mRNA level in skeletal

muscles (152). Thiazolidinediones stimulate *UCP2* expression in rat or human skeletal muscle cells in culture (153,154). A positive effect of a PPAR $\beta$  agonist on *UCP3* mRNA levels in rat L6 myotubes was obtained (155). Chevillotte et al. demonstrated that omega-6 polyunsaturated fatty acids, acting through PPAR $\beta$ , can stimulate *UCP2* expression in primary culture of human skeletal muscle cells (154). Fatty acids have been shown to induce *UCP2* expression in adipocyte cultures of both rodents (153,156) and humans (157).

A survey of articles reporting on *UCP2* or *UCP3* mRNA levels in humans does not give a clear picture. Identical (78,158) or reduced *UCP2* gene expression was measured in skeletal muscle (159) and intraperitoneal adipose tissue (160) of human obese subjects compared to lean individuals. Although body mass index was negatively correlated with *UCP2* expression in skeletal muscle of Pima Indians (161), in two other studies it was found that *UCP3* mRNA levels in skeletal muscle did not differ between obese and lean subjects (78,162). However, a prolonged hypocaloric diet downregulated *UCP3* mRNA expression in muscle of obese patients (162). No difference in the mRNA level of *UCP2* in skeletal muscle was measured between NIDDM and control subjects; in contrast, mRNA levels of *UCP3* is significantly reduced in skeletal muscle of NIDDM patients (163).

In comparison with untrained subjects, exercise-trained subjects exhibit lower levels of *UCP3* mRNA in their skeletal muscle (141). These data led the authors to hypothesize that endurance training makes athletes more energy efficient. The status of *UCP2* and *UCP3* was also investigated in skeletal muscle of tetraplegic subjects before and after an 8-week exercise program consisting of electrically stimulated leg cycling (164). In agreement with data of able-bodied people trained to physical exercise (141), tetraplegia was shown to be associated with increased expression of *UCP2* and *UCP3* in skeletal muscle, and exercise training of tetraplegic patients normalized *UCP2* mRNA levels. Although it is difficult to understand the significance of decreased *UCP* expression during exercise and increased *UCP* expression in absence of exercise, it appears that physical activity regulates *UCP* expression in skeletal muscle. Whether expression of *UCP2* and *UCP3* in skeletal muscle is related to oxygen utilization remains to be investigated.

In conclusion, an unclear picture emerges from analysis of *UCP2* and *UCP3* expression in physiological or pathophysiological situations. On the one hand, the upregulation of the *UCPs* in skeletal muscle during starvation, as well as the level of mRNAs in obese

individuals compared to lean individuals do not illustrate an obvious role for *UCP2* or *UCP3* in substrate utilization and energy partitioning. On the other hand, the positive effect of T3, a hormone known to induce mitochondrial proton leak and substrate oxidation, on expression of *UCP2* and *UCP3* in tissues, supports their possible role in energy dissipation. Analysis of *UCP2* and *UCP3* function in nonactive or activated skeletal muscle of tetraplegic patients indicates that a role for the *UCPs* in thermogenesis and maintenance of body temperature cannot be ruled out.

#### D Studies from Transgenic Mice

Mice overexpressing human *UCP3* in skeletal muscle were created (165). These mice weigh less than the wild-type littermates although they are hyperphagic. The predominant factor contributing to reduced body weight is a 50% decrease in the amount of adipose tissue in the transgenic mice. Moreover, these mice exhibit a lower insulinemia and lower fasting glycemia. Muscle temperature is increased but core temperature is not affected. The resting oxygen consumption of the transgenic mice is markedly increased. These data support a role for *UCP3* in activating substrate oxidation and decreasing body fat content. A decrease in respiratory control ratio illustrated by increased state 4 respiration and decreased membrane potential in mitochondria isolated from muscle of the transgenic animals, confirms that overexpression of *UCP3* induces respiration uncoupling. These data are in agreement with a respiration uncoupling activity of a high level of *UCP3* and its potential role in treatment of obesity. However, a critical point seems to be the question of the amount of *UCP3* necessary to induce a significant respiration uncoupling and have an effect on body weight, since Clapham et al. (165) created mice with a very high level of *UCP3*. Curiously, the same authors concluded that *UCP3* in normal mice had no uncoupling activity since *UCP3* induction in skeletal muscle of starved rats does not change the mitochondrial proton conductance (96). Moreover, it was shown that treatment of rats by T3 increases mitochondrial ATP production in oxidative muscle despite increased expression of *UCP3* (166). No data corresponding to transgenic mice overexpressing *UCP2* have been published yet.

Coincident with the creation of transgenic mice overexpressing *UCP3*, two other teams inactivated *UCP3* by gene targeting (167,168). In contrast to the marked decrease in fat content of mice overexpressing *UCP3* (see above), the *Ucp3*<sup>-/-</sup> mice are not obese; they have a normal body temperature and no change in oxygen

consumption. The absence of phenotype is surprising since analysis of the mitochondria of the *Ucp3*  $-/-$  mice showed a reduced proton leak (167), a decreased state 4 respiration, and increased ROS production (168), these three changes supporting the hypothesis of respiration uncoupling activity of UCP3. Moreover, the rate of ATP synthesis, measured by NMR analysis, is strongly increased in skeletal muscle of *Ucp3*  $-/-$  mice, and this increased efficiency of ATP production in mutant mice is consistent with a role for the uncoupling activity of UCP3 in skeletal muscle in vivo in controlling energy status (169). Therefore, the data obtained from mice made null for the UCP3 gene are rather contradictory, since it appears that disruption of a mitochondrial protein able to uncouple respiration does not induce phenotypic changes.

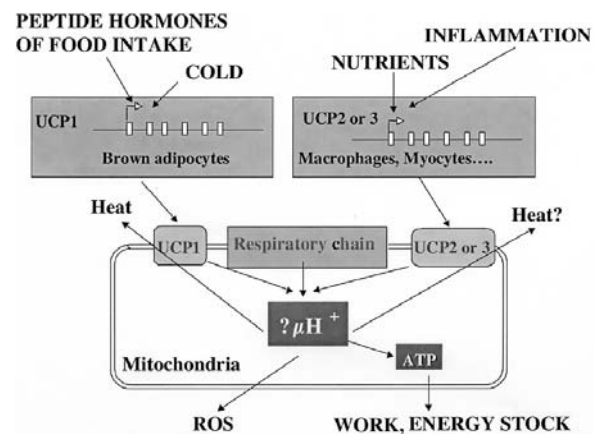

Similar to the observation with *Ucp3*  $-/-$  mice, the disruption of the UCP2 gene did not induce obesity of the mice, even when they were put on an adipogenic diet (105,170). These data challenge the expected role of the novel UCPs in energy metabolism. However, analysis of the *Ucp2*  $-/-$  mice identified two interesting roles of UCP2. Guided by the fact that UCP2 is expressed at high level in the immune system (73), Arsenijevic et al. found that the mutant mice were more resistant to infection by a parasite (170). In fact, disruption of the *Ucp2* gene provokes an elevation of ROS level that facilitates the killing of the pathogens. It is unknown whether such an effect results directly from a net change in respiration coupling in mitochondria or from a modification of the mitochondrial membrane potential that controls mitochondrial ROS production. Moreover, whether the increase of ROS in macrophages of *Ucp2*  $-/-$  mice represents the main effect on pathogens or precedes an activation of NADPH oxidase in phagocytes remains to be studied. These data support a role for UCP2 in limiting ROS level in cells as predicted (171,172). In other respects, Zhang et al. observed that the *Ucp2*  $-/-$  mice were hypoglycemic and hyperinsulinemic (105). This is due to a higher insulin secretion in response to glucose by pancreatic islets. The authors explained this higher insulin secretion as a consequence of increased ATP levels in the absence of UCP2 uncoupling activity in islets of mutant mice. The more pronounced insulin secretion by pancreatic islets of the *Ucp2*  $-/-$  mice was confirmed in another study (Picard et al., unpublished data). These data are in agreement with experiments of overexpression of UCP2 in pancreatic islets (see above). Therefore, UCP2 controls negatively insulin secretion.

To summarize studies from genetically modified mice, strong overexpression of UCP3 or deletion of

the UCP3 gene or the UCP2 gene tends to support an uncoupling activity of UCP3, but the in vivo uncoupling activity of UCP2 is still a matter of debate. Whereas disruption of the UCP3 gene did not clarify its physiological role, disruption of the UCP2 gene reveals its significant physiological role both in the control of ROS production and insulin secretion.

## E UCP2 and UCP3, Conclusions and Perspectives

Besides UCP1, which has a well-demonstrated uncoupling activity and an essential role in maintenance of body temperature in small rodents exposed to the cold, the exact biochemical and physiological roles of UCP2 and UCP3 remain to be further identified. Certain data support a true activity of these UCPs in respiration uncoupling; other data do not agree with a role for these UCPs in controlling body weight or adiposity. Whereas the physiological role of UCP3 remains rather unknown, UCP2 and UCP3 appear to be genes limiting ROS level in cells and UCP2 as a gene controlling insulin secretion.

**Figure 2** Models of physiological activities of UCP1, UCP2, and UCP3. The *UCP1* gene is only transcribed in brown adipocytes. The *UCP1* gene is activated following exposure of animals to the cold whereas the activity of the *UCP2* and *UCP3* genes can be modulated in response to the flux of glucidic or lipidic substrates. The activity of the *UCP2* gene can also be activated during inflammatory responses in macrophages. Activated UCPs tend to decrease the mitochondrial proton gradient. This gradient controls ATP synthesis and ROS production. Physiologically, the main effects of UCP1 are substrate oxidation and regulatory thermogenesis. The roles of UCP2 and UCP3 in cellular thermogenesis and control of ATP level require further studies. These two UCPs decrease ROS production by mitochondria.

Since UCP2 and UCP3 homologues exist in ectothermic animals, it may be hypothesized that UCP2 and UCP3 are closer to a UCP ancestor than is UCP1, which only exists in mammals. The UCPs belong to the family of the mitochondrial anion carriers. UCP1 translocates protons, whereas UCP2 and UCP3 can also transport protons. The ability of UCP2 and UCP3 to transport ions other than protons should be investigated. A depiction of the putative functions for the UCPs is provided in Figure 2.

Undoubtedly, a central question is that of the amount of UCP2 and UCP3 in tissues. Experiments of overexpression of the novel UCPS in transgenic mice or mammalian cells have shown that these proteins can uncouple respiration from ATP synthesis and therefore represent putative targets for antiobesity compounds. However, the amount of UCP2 or UCP3 normally present in vivo seems to be very low and insufficient to provoke a discernible uncoupling of respiration. It remains to be determined whether the amount (or activity?) of UCP2 or UCP3 in cells can be sufficiently elevated to uncouple respiration under selective natural or pharmacological conditions. The observation that the level of UCP2 protein can be rapidly and strongly increased in tissues in absence of variation in the amount of *UCP2* mRNA indicates that a rather high level of UCP2 can be obtained, at least in certain cells. It should not be forgotten that a very small, but prolonged, change in level of coupling of mitochondrial respiration, i.e., change in efficiency of substrate oxidation, can significantly affect body adiposity.

## Peroxisome Proliferator–Activated Receptor $\gamma$ and the Transcriptional Control of Adipogenesis and Metabolism

Lluís Fajas and Johan Auwerx

Institut de Génétique et de Biologie Moléculaire et Cellulaire, Illkirch, and Université Louis Pasteur, Strasbourg, France

### I INTRODUCTION

The peroxisome proliferator–activated receptor gamma (PPAR $\gamma$ ) is one of three PPARs, which together constitute a distinct subfamily of the nuclear receptor superfamily and which are all activated by naturally occurring fatty acids or fatty acid derivatives. PPAR $\gamma$  heterodimerizes with retinoid X receptors (RXR) and alters the transcription of numerous target genes after binding to specific response elements or PPREs, which are found in several genes involved in fat metabolism. Coordinate regulation of genes involved in fat uptake and storage by PPAR $\gamma$  underlies its effects on adipocyte differentiation. PPAR $\gamma$ 's claim to fame is due to its pivotal roles in adipogenesis and its implication in insulin sensitization. A number of additional functions were attributed to PPAR $\gamma$ , which suggests a more pleiotropic role affecting multiple fundamental pathways in the cell with wide-ranging biomedical implications.

### II THE PPAR $\gamma$ GENE, RNA, AND PROTEIN

The human PPAR $\gamma$  gene, which is mapped to a locus on chromosome 3p25, has nine exons and spans over 100 kb of genomic DNA (1). In contrast to mice, in which only two PPAR $\gamma$  isoforms have been described

so far (2), in man, three PPAR $\gamma$  mRNA isoforms have been identified—PPAR $\gamma$ 1,  $\gamma$ 2(1), and  $\gamma$ 3 (3). Alternate transcription start sites and alternative splicing generate these three PPAR $\gamma$  mRNAs, which differ at their 5' ends. Consistent with the production of three PPAR $\gamma$  mRNAs, there are three PPAR $\gamma$  promoters, each with a specific and distinctive expression pattern, (1,3). Whereas the PPAR $\gamma$ 1 and  $\gamma$ 3 mRNAs give rise to an identical protein product, i.e., PPAR $\gamma$ 1, the PPAR $\gamma$ 2 mRNA encodes for the PPAR $\gamma$ 2 protein, which in man contains 28 additional amino acids encoded by the B exon.

Little is known about the expression of PPAR $\gamma$  during development in mammals (4). In adult animals, PPAR $\gamma$  expression is relatively confined. Adipose tissue, large intestine, and hematopoietic cells express the highest levels of PPAR $\gamma$ ; kidney, liver, and small intestine have intermediate levels; whereas PPAR $\gamma$  is barely detectable in muscle (1,5). Related to the subtype distribution, PPAR $\gamma$ 2 is much less abundant in all tissues relative to PPAR $\gamma$ 1, the predominant PPAR $\gamma$  form. The only tissue expressing significant amounts of PPAR $\gamma$ 2 is adipose tissue, where PPAR $\gamma$ 2 mRNA makes up 30% of total PPAR $\gamma$  mRNA (5). PPAR $\gamma$ 3 mRNA expression is restricted to macrophages and large intestine (3,6).

In man, short-term changes in food intake do not affect the expression levels of PPAR $\gamma$  (5), whereas

hypocaloric diets for a longer period result in a down-regulation of PPAR $\gamma$  expression (7). In rodents, PPAR $\gamma$  was downregulated by fasting and insulin-dependent diabetes mellitus (8), whereas its expression was induced by a high-fat diet. Most interesting, however, was the observation that in normal-weight subjects PPAR $\gamma$  expression is highly enriched in subcutaneous fat, whereas its expression in visceral adipose tissue is significantly higher in obese subjects (9). Insulin and glucocorticoids induce PPAR $\gamma$  expression in cultured human adipocytes (7,10), whereas TNF $\alpha$  was reported to decrease PPAR $\gamma$  expression (11,12).

### III SOME STRUCTURAL ISSUES

As in all nuclear receptors (NRs), PPAR $\gamma$  has a modular structure composed of several domains: the NH<sub>2</sub> terminal A/B domain, harboring a ligand-independent transcriptional activation function (AF-1); the C domain, which contains two zinc fingers, responsible for DNA binding; the D or hinge region, which is important for cofactor docking; and the E COOH-terminal region, which among others contains the ligand-binding domain (LBD) and the ligand-dependent activation domain AF-2 (reviewed in 13). In recent years a large body of information has accumulated related to the three dimensional structures of the LBDs of multiple NRs (14). In general, the unliganded (apo) LBD of a prototypical NR is organized in 12 highly conserved  $\alpha$ -helices which are folded into three layers to create a central hydrophobic ligand-binding pocket. The x-ray crystallographic structures of the LBD of PPAR $\gamma$  are similar to those reported for the other receptors (15,16).

The ligand-binding pocket of PPAR $\gamma$  is formed by residues from helix (H), 2', H3, H5, H7, H11, H12, and the  $\beta$ -sheet (Fig. 1). In contrast to the LBDs of other NRs, the PPAR $\gamma$  ligand-binding pocket is exposed to the solvent between H3 and the  $\beta$ -sheet, and PPAR $\gamma$  has a more accessible ligand-binding cavity, which at  $\approx 1300 \text{ \AA}^3$  is almost twice the size of that of other receptors ( $\approx 600 \text{ \AA}^3$ ) (15–17). The PPAR $\gamma$  apo-LBD (unliganded receptor) has a highly dynamic character, and agonist binding leads to a strong decrease of conformational freedom (18). In the crystal structure of the PPAR $\gamma$  apo-LBD homodimer (15), the activation helix H12 extends one subunit away from the LBD core, as in the RXR apo-LBD (19), while in the other subunit H12 is packed against the LBD core, sealing the pocket on one side, as in the retinoic acid receptor (RAR) boro-LBD (liganded form) (20). This

**Figure 1** Crystallographic structure of the ternary complex hPPAR $\gamma$  LBD homodimer/rosiglitazone/coactivator peptide ((27) and PDB entry 2PRG). One LBD monomer is in green and the other one in yellow. Helices are depicted as cylinders and  $\beta$ -strands as arrows. In one monomer (the green one), residues 239–247 and 257–272 are not seen in the electron density map, and thus s0 and H2' are not present. Rosiglitazone is in blue and the coactivator peptide is depicted as a red ribbon. Only the NR boxes of the coactivator peptide are seen in the electron density map; each NR box forms a helix that fits in a hydrophobic cleft on the LBD surface comprising the C-terminus of H3, loop H3-H4, H4, and H12.

indicates that H12 is in equilibrium between at least these two conformations that are trapped by the crystal packing. In the PPAR $\gamma$  (16) apo-LBD monomer structure, H12 is also in a “hololike” conformation, folded against the LBD core. The structure of rosiglitazone-bound PPAR $\gamma$  LBD homodimer as a ternary complex with a fragment of the SRC-1 coactivator has also been reported (15). Rosiglitazone occupies  $\sim 40\%$  of the ligand-binding pocket and is stabilized there by a combination of hydrogen bonds and Van der Waals contacts. The SRC-1 fragment contains two conserved LXXLL motifs (“NR boxes”) with each LXXLL motif bound to one LBD monomer (21–23). The helix of the LXXLL peptide is positioned in a hydrophobic cleft on the LBD surface, formed by H3, the loop H3-H4, H4, and H12, through what has been called a “charge clamp.” When H12 is in a hololike conformation in the PPAR $\gamma$  apo-LBD crystal structures, its position is slightly different from that in the agonist-bound structure. This emphasizes the crucial role of the direct or indirect contacts between the ligand and H12 in the transactivation process. The bound agonist tightens the position of H12 to provide

a precise anchoring surface for the coactivator together with H3-H4. Interestingly, in the structure with the partial agonist GW0072, H12 does not seem to interact directly with the ligand and hence is found in a position more similar to the unliganded (apo) than to the liganded (holo) structure (24). Unlike full agonists, partial agonists would therefore not be able to stabilize the activation helix in the proper position, owing to the lack of a few key interactions, and such a slight malpositioning of H12 may result in an attenuated transcriptional response.

Recently, the structure of a PPAR $\gamma$ -RXR $\alpha$  LBD heterodimer was reported (25). The heterodimerization interface is topologically the same as the homodimerization interface in RXR (19), ER (26), and PPAR (15), and as the heterodimerization interface in the RAR $\alpha$ -RXR $\alpha$  heterodimer (27). An interesting feature is the salt bridge between the C-terminal carboxylate of PPAR $\gamma$  (Tyr477, 4 residues downstream of H12) and Lys431 in H10 of RXR $\alpha$ . In the case of heterodimers, transcription may be regulated by the respective ligands for both receptors, such as is the case in the permissive PPAR-RXR heterodimer, whereas this is not the case for the nonpermissive RAR-RXR and TR-RXR heterodimers (28). The interaction between the C-terminus of the PPAR $\gamma$  LBD and H10 of RXR suggests a structural basis for such permissiveness, as it may stabilize H12 of PPAR $\gamma$  in the holo conformation allowing the recruitment of coactivators, even in the absence of a bound agonist (25).

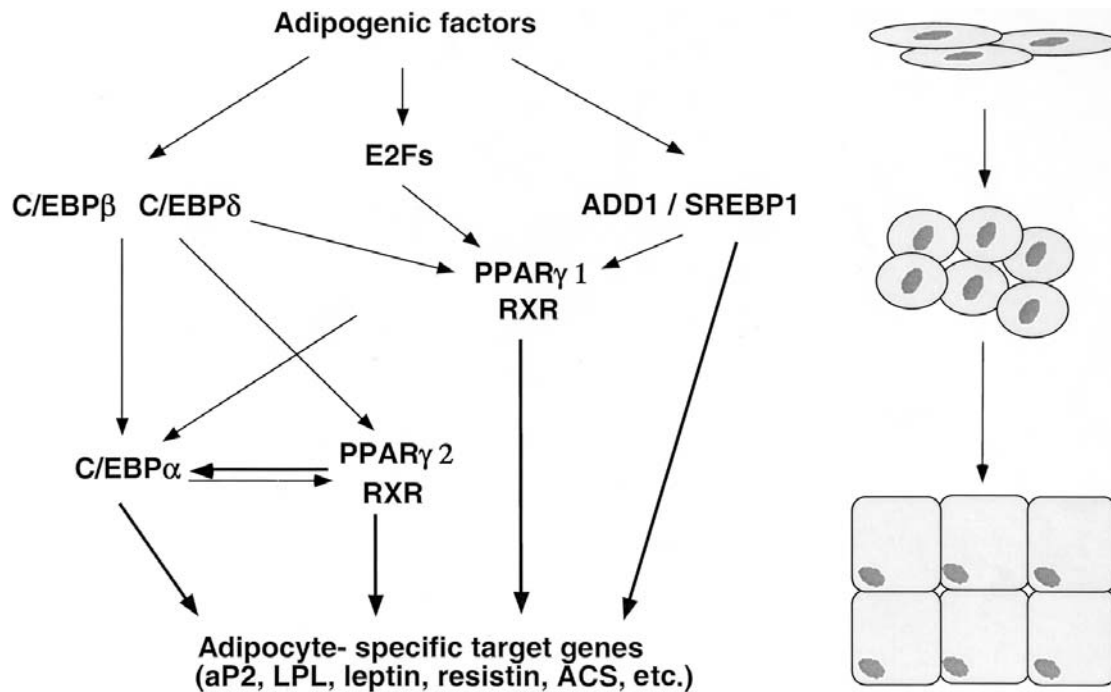

#### IV A COORDINATOR FOR THE THRIFTY RESPONSE

Adipose tissue is mainly composed of adipocytes, which store energy in the form of triglycerides during periods of nutritional affluence and release it as free fatty acids at times of nutritional deprivation (for review see 29,30). Excessive accumulation of adipose tissue leads to obesity, whereas its absence is associated with lipodystrophic syndromes. The molecular mechanisms that control adipocyte differentiation from adipose precursor cells (adipoblasts) are complex and are affected by numerous signaling pathways. The adipocyte differentiation process starts after fibroblastic precursor cells become contact-inhibited in their growth. Those cells then re-enter the cell cycle after appropriate hormonal induction, in a process termed clonal expansion. Later on, cells arrest this second proliferation phase again, undergo terminal adipocyte differentiation, and start to accumulate

lipids (Fig. 2). We will discuss these two phases separately in the sections below.

#### A Control of the Early Phases of Adipogenesis

Whereas the terminal stages of adipocyte differentiation are well understood, the molecular mechanisms underlying the transition between cell proliferation and differentiation of preadipocytes remain elusive. Since these early phases of adipogenesis involve clonal expansion of the precursor cells, it was logical to start looking for factors that are involved in the control of the cell cycle as potential triggers for these early phases. The E2F family of transcription factors, which are major regulators of the cell cycle and which have been shown to have an important role in the regulation of other differentiation systems, were hence good candidates (31–33). E2Fs trigger the expression of PPAR $\gamma$  directly by binding to and transactivating the PPAR $\gamma$  promoter during the clonal expansion of the adipocyte differentiation process. In contrast to E2Fs, the role of the retinoblastoma (RB) protein family members, or the pocket proteins RB, p130, and p107, in adipocyte differentiation seems more complex. The negative role of pocket proteins in cell cycle progression, repressing the expression of the E2F target genes, has been demonstrated in several settings (for review see 34,35). Pocket proteins are inactivated by phosphorylation by the cyclin-dependent kinases, resulting in the activation of the E2F target genes. Consistent with an active cell cycle in the early stages of adipogenesis, pocket proteins have been found to be hyperphosphorylated following hormonal induction of preadipocytes (36). However, an apparent paradox arises from the finding that pRB inactivation by SV40 large T-antigen inhibits adipogenesis (37). Moreover, pRB-deficient fibroblasts fail to differentiate into adipocytes when properly stimulated (38,39). This apparent paradox was explained by the participation of RB in the growth arrest following clonal expansion (39a). This suggests that RB is involved in two phases of adipocyte differentiation. First, inactivation of RB enables clonal expansion, whereas growth arrest after this expansion phase requires active RB, which positively influences adipocyte differentiation. A different role, independent of the control of cell cycle, has also been attributed to RB in another aspect of the regulation of adipogenesis, i.e., the enhancement of the transactivation capability of C/EBP $\alpha$  and  $\beta$ , via direct protein-protein interaction (39). In contrast to RB, the other members of the retinoblastoma family, p130 and p107, have been

**Figure 2** Coordinate regulation of adipogenesis by E2Fs, PPAR<sub>γ</sub>, C/EBPs, and ADD-1/SREBP-1. Interactions among these different transcription factors determine the cascade of events during adipocyte differentiation. The right part of the figure depicts the three different cellular stages—adipocyte precursors, adipoblasts, and adipocytes. The quiescent adipocyte precursor cells undergo an obligatory phase of clonal expansion which requires reentry into the cell cycle. This phase generates adipoblasts, which upon further lipid accumulation become mature adipocytes.

reported to negatively regulate adipogenesis (36,38). Indeed, fibroblasts deficient in both p130 and p107 differentiate spontaneously into adipocytes, whereas the wild-type cells do not (38). Furthermore, reintroduction of p130 and p107 in these cells inhibits adipocyte differentiation. These effects of p107 and p130 in adipogenesis have been suggested to be mediated through downregulation of PPAR<sub>γ</sub> activity.

In the context of the early phases of adipocyte differentiation, we will now discuss the transcriptional regulators that have been shown to inhibit adipogenesis. The adipocyte enhancer-binding protein 1 (AEBP-1) is a carboxypeptidase which was first described as a transcriptional repressor that inhibits the expression of the adipocyte fatty acid-binding protein aP2 (40). Expression of AEBP-1 is downregulated during the adipocyte differentiation process (40). Recently, it was shown that the  $\gamma 5$  subunit of the heterotrimeric G protein binds to AEBP-1 and that it attenuates its transcriptional repression activity (41). Adipogenic stimulation selectively decreased G $\gamma 5$  level and enhanced the transcriptional

repression activity of AEBP-1 during the mitotic clonal expansion at the onset of adipogenesis (41). Which set of genes is inhibited by this increased AEBP-1 activity during clonal expansion phase is at present unknown, but it is tempting to speculate that some of the genes driving terminal adipocyte differentiation, such as PPAR<sub>γ</sub> and the C/EBP family of transcription factors, could be AEBP-1 targets.

It has been suggested that adipogenesis is also inhibited by several transcription factors of the GATA-binding protein family (42). GATA-2 and -3 are strongly and selectively expressed in adipose tissue (42). Although these GATA factors are enriched in adipose tissue, there is good evidence that they play a negative role in adipogenesis. This is based on the observation that in four independent mouse models of obesity, including the *ob/ob*, *db/db*, and *tub/tub*, and *KK<sup>A</sup>* mice, expression of GATA-2 and GATA-3 was decreased in adipose tissue (42). Constitutive expression of GATA-2 and GATA-3 results furthermore in a decrease in PPAR<sub>γ</sub> expression and a consequent

inhibition of adipocyte differentiation (42). This effect is mediated by a direct inhibitory effect of these GATA factors on PPAR $\gamma$  transcription. Consistent with such an inhibitory effect of GATA-3 on adipocyte differentiation, it was shown that GATA-3  $-/-$  embryonic stem cells differentiated much more efficiently into adipocytes than wild-type ES cells (42).

The retinoic acid receptor (RAR) is another transcription factor of the NR family that is capable of blocking early steps of adipocyte differentiation. In fact, downregulation of RAR $\gamma$  1 expression during adipocyte differentiation correlates well with the loss of responsiveness to the inhibitory effects of retinoic acid on adipocyte differentiation (43). Along similar lines, ectopic expression of RAR extends the retinoic acid responsive period (43). One mechanism by which retinoic acid might block adipogenesis is by interfering with C/EBP $\beta$ -mediated transcription, which is only essential in the early stages of adipogenesis (44), thereby explaining why retinoic acid is less effective when added later in the adipocyte differentiation program. In addition, retinoic acid can inhibit PPAR $\gamma$  action by favoring the formation of the nonpermissive RAR/RXR heterodimer over the PPAR/RXR dimer (45) (see also Fig. 2). Alternatively, RA has been shown to induce the expression of the repressive orphan receptor COUP-TF (46), which also competes with PPAR $\gamma$  for binding to a DR-1.

Several other signaling pathways have been suggested to inhibit this early phase of adipogenesis; tumor necrosis factor alpha (TNF)- $\alpha$ , Pref-1, and Wnt. TNF $\alpha$  is a potent inhibitor of adipocyte differentiation and exposure of 3T3-L1 adipocytes or primary adipocytes to TNF $\alpha$  results in lipid depletion and a complete reversal of adipocyte differentiation (47). An important mechanism by which TNF $\alpha$  exerts its antiadipogenic action is downregulation of the expression of adipogenic factors such as C/EBP $\alpha$  (48,49) and PPAR $\gamma$  (11,47). Interestingly, several other polypeptides, such as TGF $\beta$  and bFGF, as well as PKC-activating agents and calcium ionophores, are capable of reversing adipocyte differentiation through a decreased expression of adipogenic transcription factors (11,50). How these agents mediate this decrease in expression is unclear, but further studies are required to investigate the role of NF- $\kappa$ B, AP1, and other transcription factors in the inhibition and reversal of adipocyte differentiation.

Pref-1 is a 45 to 60 kDa transmembrane protein with six tandem EGF-like repeats, which has some similarities to the *Drosophila* cell-fate determination proteins Notch and Delta (51). Pref-1 is expressed in preadipocytes but is absent in adipocytes (51), and its constitui-

tive expression inhibits expression of PPAR $\gamma$  and C/EBP $\alpha$  and blocks adipocyte differentiation (52), suggesting that it functions as a negative regulator of adipogenesis. The inhibitory action of Pref-1 can be exerted either in a juxtacrine manner, as a transmembrane protein affecting adjacent cells, or in a paracrine manner, as a soluble inhibitor of adipocyte differentiation, released by cleavage of the membrane-associated form (52). There are four major forms of Pref-1 which result from alternate splicing (53). Although all four transcripts generate transmembrane Pref-1, only two of them undergo processing to a soluble form of Pref-1, corresponding to their respective complete ectodomains. The other two Pref-1 proteins have a deletion that includes the putative processing site proximal to the membrane, and therefore do not produce a soluble form (53). The mode of inhibition, i.e., juxtacrine or paracrine, therefore depends on the specific alternate Pref-1 form expressed, and underscores the importance of alternate splicing in the determination of Pref-1's range of action (53). However, the mechanism of action of Pref-1 or which signaling pathway is implicated remains to be elucidated. Some pro-adipogenic hormones, such as dexamethasone, have been shown to inhibit expression of Pref-1 (54).

Finally, the Wnt family of signaling factors also negatively affects adipocyte differentiation (55). Wnts, signaling molecules that play a major role in the regulation of cell growth and development (56), have been implicated in the inhibition of adipocyte differentiation. It was recently demonstrated that forced expression of Wnt-1 in 3T3-F442A cells inhibited the formation of adipose tissue when these cells were grafted into nude mice (55). Furthermore, 3T3-L1 cells ectopically expressing a dominant negative form of TCF4, a transcriptional mediator of Wnt signaling, undergo adipogenesis without any hormonal induction (55). Repression of PPAR $\gamma$  and C/EBP $\alpha$  expression was suggested as the mechanism by which activation of the Wnt signaling inhibited adipogenesis.

## B The Terminal Phases of Adipocyte Differentiation

The terminal phases of adipogenesis are relatively well understood (for review see 30,57), and it is at this stage that PPAR $\gamma$  is suggested to be the predominant player. This was initially based on the fact that the infection of fibroblasts with a retrovirus encoding PPAR $\gamma$ -induced fibroblast (58) and muscle cells (59) undergo terminal adipocyte differentiation. This adipogenic property, however, seems hardly unique, since a whole range of

transcription factors affect adipogenesis. It is currently thought that full-fledged adipogenesis requires an interplay between the PPAR $\gamma$ /RXR heterodimer and two other groups of transcription factors: the CCAATT enhancer-binding proteins (C/EBP), and ADD-1/SREBP-1 (reviewed in 29,30) (Fig. 2). Although all of these transcription factors can independently induce adipocyte differentiation *in vitro*, they act synergistically *in vivo*.

During the initial phases of these terminal stages of adipogenesis, C/EBP $\beta$  and  $\delta$  are induced in response to adipogenic hormones such as insulin or glucocorticoids (60–62). Both these C/EBPs induce the transcription of PPAR $\gamma$ 2, via interaction with a C/EBP site in the PPAR $\gamma$ 2 promoter (63). Ectopic expression of C/EBP $\beta$  is sufficient to induce differentiation of 3T3-L1 cells in the absence of hormonal induction, whereas overexpression of C/EBP $\delta$  accelerates adipose conversion, but only in the presence of hormonal inducers (60). Furthermore, induction of C/EBP $\beta$  levels results in the differentiation of NIH-3T3 fibroblasts, which cannot differentiate spontaneously. Additional evidence that both these C/EBPs play an important role in the control of the adipocyte differentiation process *in vivo* comes from the characterization of animals with mutations in the C/EBP $\beta$  and  $\delta$  genes. Mice lacking either of these factors have normal white adipose tissue, although their brown adipose tissue accumulates less lipids (64). The reduced fraction of mice (15%) that survive the deletion of both C/EBP $\beta$  and  $\delta$  genes have a severe decrease in both brown and white adipose tissue mass, despite normal levels of expression of PPAR $\gamma$  and C/EBP $\alpha$  (64). In contrast to the role of C/EBP $\beta$  and  $\delta$  in regulating the expression of PPAR $\gamma$ 2, expression of PPAR $\gamma$ 1 seems to be independent of these factors. Indeed, a dominant negative C/EBP $\beta$  isoform (also termed LIP) suppresses adipogenesis and the expression of PPAR $\gamma$ 2, whereas PPAR $\gamma$ 1 was still expressed (65). However, addition of PPAR $\gamma$  agonists bypassed the block in adipogenesis imposed by LIP, suggesting that C/EBP $\beta$  might not only induce the expression of PPAR $\gamma$ 2 (63), but also participates in the generation of PPAR $\gamma$  ligands during adipogenesis (65).

RXR, the obligate heterodimeric partner of PPAR $\gamma$ , constitutes another pivotal sensor during adipocyte differentiation (45). On DR-1 response elements, such as most PPREs, RXR is a nonpermissive inactive partner when heterodimerized with RAR, whereas it is a permissive partner in the context of the PPAR $\gamma$ /RXR heterodimer. The levels of RAR and PPAR $\gamma$  change

considerably during the induction of adipocyte differentiation, with RAR expression being strongly reduced and PPAR $\gamma$  levels being induced (43). A change in the relative levels of RAR and PPAR $\gamma$  in the differentiating adipocytes will hence induce a switch for RXR from one partner to another one (43,45). This will change RXR activity from the nonpermissive state when bound to RAR to the permissive state when complexed to PPAR $\gamma$ . This switch in partners induces the recruitment of a distinct set of cofactors, ultimately translating in an alteration of the transcriptional activity of the downstream target genes (Fig. 3) (45). Such a switch in partners might underlie not only how PPAR $\gamma$  agonists but also how RXR agonists exert their effects on adipogenesis and glucose homeostasis. Proof that RXR is involved in adipose tissue homeostasis *in vivo* was recently provided by the spatiotemporally controlled mutagenesis of the RXR $\alpha$  gene in adipose tissue (66). Mice lacking RXR $\alpha$  in fat tissue have significantly reduced fat mass and are resistant against the induction of obesity (66). This model further points out that most likely both partners of the RXR/PPAR $\gamma$  heterodimer are important in inducing and maintaining adipose tissue homeostasis.

The basic helix-loop-helix (bHLH) protein ADD-1/SREBP-1c is also induced during terminal adipocyte differentiation (67,68). ADD-1/SREBP-1c accelerates

**Figure 3** Switch in RXR partners stimulates adipocyte differentiation. PPAR/RXR and RAR/RXR heterodimers respectively activate and repress DR-1 containing promoters. When the RAR/RXR heterodimer is bound to a DR-1, RAR blocks the binding of ligands to RXR, keeping the heterodimer in an inactive state due to the binding of corepressors such as N-CoR or SMRT. In contrast, the PPAR/RXR heterodimer configuration permits ligand binding to RXR, allowing for activation of both partners in the PPAR/RXR heterodimer.

adipocyte differentiation when coexpressed in fibroblasts, which also contain PPAR $\gamma$ . ADD-1/SREBP-1 belongs to a family of transcription factors that are synthesized as membrane-bound precursors that are released by proteolysis (69). Whereas the proteolytic cleavage of SREBP-2 is regulated by cellular cholesterol levels, it is at present unknown what controls the cleavage of ADD-1/SREBP-1 (69). ADD-1/SREBP-1c induces the expression of several genes involved in lipogenesis in both adipocytes and liver. These genes include the genes encoding for fatty acid synthase (68,70,71), acetyl coenzyme A carboxylase (71,72), glycerol-3-phosphate acyltransferase (73), and the lipoprotein lipase (LPL) gene (68,71) (74). Stimulation of lipogenesis contributes to the massive cholesterol and fatty acid accumulation seen in the livers of transgenic animals expressing the mature form of SREBP-1a (71), and to the more moderate fatty acid accumulation observed upon overexpression of the weaker transactivator SREBP-1c (75). The observation that transgenic mice overexpressing SREBP-1c under the control of the adipose tissue-specific aP2 promoter are lipodystrophic (76) appears inconsistent with these adipo- and lipogenic effects (68,71,75) and suggests that SREBP-1c, under certain conditions, could also negatively influence adipogenesis. The differences between this last study (76) and previous work (68,71,75) are unclear and will require further investigation.

Finally, terminal adipocyte differentiation requires the concerted action of PPAR $\gamma$  and C/EBP $\alpha$  (58,59, 77), another C/EBP family member which appears only relatively late in the differentiation process. In contrast to the relatively early effects of C/EBP $\beta$  and  $\delta$ , C/EBP $\alpha$  seems to play an important role in the later stages of differentiation by sustaining high levels of PPAR $\gamma$  expression and by maintaining the differentiated adipocyte phenotype. Several lines of evidence support an important role of C/EBP $\alpha$  in adipocyte differentiation. First, temporal activation of C/EBP $\alpha$  expression occurs immediately before the coordinate expression of a group of adipocyte-specific genes, suggesting its involvement in their regulation. Second, antisense C/EBP $\alpha$  RNA can inhibit adipocyte differentiation. Third, premature induction or overexpression of C/EBP $\alpha$  triggers adipocyte differentiation. And finally, adipocytes from C/EBP $\alpha$   $-/-$  mice failed to accumulate lipids in adipose tissue (78,79). PPAR $\gamma$  controls not only the expression of C/EBP $\alpha$ , but this last factor in its turn also induces PPAR $\gamma$  gene expression, via interaction with C/EBP response elements present in the human (63) and mouse (2,77) PPAR $\gamma$  promoter. Interestingly, introduction of PPAR $\gamma$  in cells deficient for

C/EBP $\alpha$  enabled adipocyte differentiation, whereas the reverse, i.e., overexpression of C/EBP $\alpha$  in PPAR $\gamma$  deficient cells, did not result in differentiation.

## C Other Factors Involved in Adipogenesis

### 1 Signal Transducers and Activators of Transcription (STATs)

The STAT family of transcription factors is composed of six family members that are phosphorylated as a cellular response to various cytokines and peptide hormones (80,81). After phosphorylation and translocation to the nucleus, they regulate the transcription of specific target genes. Three members of the STAT family—STATs 1, 3, and 5a and b—are highly induced during adipocyte differentiation in a manner similar to C/EBP $\alpha$  and PPAR $\gamma$  (82). Furthermore, inhibition of adipogenesis by TNF $\alpha$  correlates with the repression of STATs in 3T3-L1 cells (82). Adipose tissue contains several receptors of the cytokine receptor superfamily, such as the growth hormone and the prolactin receptor, both of which are induced during the differentiation process (83,84) and which have been shown to control the expression of adipocyte genes, such as LPL (85,86). Interestingly, prolactin, a lactogenic hormone that triggers the STAT pathway, was shown to increase C/EBP $\beta$  and PPAR $\gamma$  mRNA expression and stimulate adipocyte differentiation of NIH-3T3 cells (87). Furthermore, it was shown that STAT5a transactivated the expression of the aP2 promoter in a prolactin-dependent manner. Further support for a role of STAT5a and b in adipogenesis came from the analysis of mice deficient in these transcription factors. Targeted deletion of either STAT5a or STAT5b results in animals with markedly reduced adipose tissue mass (88). In contrast to STAT5, participation of STAT3 in the adipocyte differentiation process seems to be restricted to the proliferative phases of the clonal expansion (89). Unfortunately, STAT3-deficient mice are not viable (90), and tissue-specific STAT3-deficient animals will be required to further assess the role of this member of the family in adipogenesis. Altogether, these data suggest that cytokines and peptide hormones, through their effects on STAT-mediated gene expression (and perhaps other transcription factors), could play a significant role in the development and/or maintenance of the adipose phenotype.

### 2 Glucocorticoid Receptor

Activated glucocorticoid receptor (GR) is thought to have multiple pro-adipogenic effects, several of them enhancing PPAR $\gamma$  activity. First, glucocorticoids in-

hibit the expression of Pref-1 (54). The transcriptional repression of Pref-1 is an early action of dexamethasone in 3T3L1 adipocyte differentiation, suggesting that downregulation of Pref-1 by glucocorticoids may be a prime mechanism for promoting adipogenesis. Second, activated GR will increase the expression of early adipogenic genes, including the C/EBPs, which in their turn will switch on PPAR $\gamma$ . It has also been suggested that GR might directly stimulate the expression of PPAR $\gamma$ , although further studies are required to elucidate whether there is a functional GR binding site in the PPAR $\gamma$  promoter. In addition, glucocorticoids are known to activate phospholipase A2, stimulating the production of prostanoid ligands of PPAR $\gamma$  (91). Another important issue to bring up at this time is the relationship between hypercortico steroidism and insulin resistance. Corticosteroid activity is in part regulated by the activity of the enzyme 11 $\beta$ -hydroxysteroid dehydrogenase (11 $\beta$ -HSD), which converts cortisone into the active glucocorticoid cortisol. Activation of PPAR $\gamma$  has been shown to reduce 11 $\beta$ -HSD activity in adipose tissue, and the ensuing decrease in cortisol levels will contribute to the antidiabetic effects of PPAR $\gamma$  activators (92).

#### D Adipocyte Apoptosis

PPAR $\gamma$  is a crucial element not only in the control of adipocyte differentiation but also in the modulation of programmed cell death in the adipocytes (93) (J. Auwerx, unpublished results). Activation of PPAR $\gamma$  has been shown to induce adipocyte apoptosis, an event mainly restricted to large fully differentiated adipocytes, which express high amounts of PPAR $\gamma$ . This pro-apoptotic effect of PPAR $\gamma$  activation on large adipocytes,

**Figure 4** Remodeling of white adipose tissue by PPAR $\gamma$  activation. Activation of PPAR $\gamma$  in adipocytes will not only translate in apoptosis of the fully differentiated adipocytes, but will also induce de novo differentiation of preadipocytes. This will result in a continuous remodeling of the adipose tissue.

coupled with its capacity to enhance de novo differentiation of adipocytes, favors the formation of small adipocytes which tend to replace the large adipocytes normally constituting white adipose tissue (93,94). It is therefore tempting to speculate that PPAR $\gamma$  activation results in a continuous remodeling of adipose tissue (Fig. 4). The ultimate fate of these small freshly differentiated adipocytes remains unclear. It will therefore be important to determine whether over time they will store more and more energy and finally become hypertrophic leading to a state of resistance to PPAR $\gamma$  activation.

#### V PPAR $\gamma$ CONTROLS ADIPOCYTE-SPECIFIC GENE EXPRESSION

The enhanced adipocyte differentiation, which ensues from PPAR $\gamma$  activation, translates in the induction of the expression of adipocyte-specific genes. In fact, functional PPRES have been identified in several genes implicated in adipocyte differentiation, most of them involved in lipid storage and control of metabolism. Good examples are the lipid-binding protein aP2 (95), phosphoenolpyruvate carboxykinase (PEPCK) (96), acyl-CoA synthase (ACS) (97), fatty acid transport protein-1 (FATP-1) (98), and LPL (99), which are all regulated by PPAR $\gamma$ . PPAR $\gamma$  can also influence and control the generation and cellular uptake of its own ligands or activators, suggesting that PPAR $\gamma$  and its target genes play an interdependent role in adipocyte differentiation. This hypothesis is supported by the observation that fatty acids and fatty acid analogs induce the expression of adipocyte-specific genes, enhance adipocyte conversion, and maintain the mature adipocyte phenotype by creating a positive feedforward loop, which involves PPAR $\gamma$  and several of the above mentioned target genes (for review see 29,30,100). Some of these adipocyte-specific genes are also coordinately regulated by the other transcription factors discussed above (74,99), resulting in a strong and sustained expression of these genes.

In addition to these genes, which are mainly involved in adipocyte metabolism, cytokinelike signaling factors produced by the adipocytes, such as leptin, TNF $\alpha$ , and resistin, also appear to be functioning in this adipocyte sustaining positive regulatory loop. Leptin is an adipocyte-derived signaling factor which after interaction with specific cytokinelike receptors induces a pleiotropic response including control of body weight and energy expenditure (reviewed in 101). Leptin gene expression is regulated in an opposite fashion by PPAR $\gamma$  and C/EBP $\alpha$ , the first one reducing its expression (102–104),

whereas the second induces its expression (105–107). The decrease in circulating leptin levels upon PPAR $\gamma$  activation is associated with an increase in food intake, which will provide substrates, subsequently to be stored in the adipocytes. A similar hypothesis can be formulated in relation to adipose tissue TNF $\alpha$  production. TNF $\alpha$ , which was originally described as cachectin, is a potent inhibitor of adipocyte differentiation, and exposure of 3T3-L1 adipocytes to TNF $\alpha$  results in lipid depletion and a complete reversal of adipocyte differentiation (108) (reviewed in 109). TNF $\alpha$  exerts this antiadipogenic action in part by the downregulation of the expression of adipogenic factors such as C/EBP $\alpha$  (48,49) and PPAR $\gamma$  (11,12,110). Interestingly, obesity characterized by increased adipose tissue mass is associated with increased TNF $\alpha$  expression in adipose tissue. Although the exact role of high TNF $\alpha$  levels in obesity is unclear, it might constitute a regulatory mechanism to limit further increase in adipose tissue mass. This increase in TNF $\alpha$  levels in obesity also interferes with the insulin signaling pathways (111), contributing to the insulin resistance characteristic of the obese state (112,113). Consistent with the opposing effects of PPAR $\gamma$  and TNF $\alpha$  in adipose tissue, treatment of obese animals with PPAR $\gamma$  agonists reduces adipose tissue expression of TNF $\alpha$ , contributing to weight gain (93,114). PPAR $\gamma$  activation furthermore blocks the inhibitory effects of TNF $\alpha$  on insulin signaling (110) as well as the TNF $\alpha$ -induced glycerol and free fatty acid release (115). PPAR $\gamma$  activation would not only favor adipocyte differentiation by affecting adipocyte metabolism, but in addition would trigger an adipocyte-sustaining endocrine, paracrine, or autocrine response consisting of decreased levels of two important adipocyte-derived signaling factors, leptin and TNF $\alpha$ . PPAR $\gamma$  therefore seems to be a master gene controlling a coordinated thrifty response.

Another adipose tissue protein whose expression has been shown to be decreased by PPAR $\gamma$  activation is resistin (116). Resistin was identified in a screen of genes downregulated by the PPAR $\gamma$  agonist rosiglitazone in fully differentiated adipocytes (116). Resistin is a secreted protein, and its levels in plasma are increased in several animal models of obesity. The group of Lazar et al. hypothesized that resistin is a signaling molecule, which reduces glucose utilization by insulin-sensitive tissues. To prove this point, it was shown that decreasing resistin levels by injection of resistin antibodies improves glucose homeostasis, whereas a deterioration of glucose homeostasis is observed after administration of recombinant resistin to animals (116). Two new resistinlike molecules, RELM $\alpha$  and RELM $\beta$ , have been

described recently (117). Interestingly, the expression pattern of these two proteins is restricted to two tissues with high levels of PPAR $\gamma$  expression, i.e., adipose tissue and colon (117). Further studies are required to elucidate the exact function of the resistin protein family, but it is highly likely that they act as signaling molecules.

## VI NATURAL AND SYNTHETIC PPAR $\gamma$ ACTIVATORS

PPAR $\gamma$ , like the other PPARs, seems to be a very promiscuous receptor when it comes to activation, which can be achieved by a wide variety of naturally occurring and synthetic compounds (118). This property could be linked to its spacious ligand-binding cavity (15,16). For some of these PPAR $\gamma$  agonists, it was subsequently shown that they not only activate, but also bind to, the receptor. Most attention has been paid to some of the naturally occurring arachidonic acid metabolites derived from the cyclooxygenase pathway, such as 15-deoxy- $\Delta$ 12,14-prostaglandin J2 (119–121) and  $\Delta$ 12-prostaglandin J2 (122). Although 15-deoxy- $\Delta$ 12,14-prostaglandin J2 was shown to be the most potent of the naturally occurring ligands, it is still unclear whether it is produced in sufficient quantities in vivo in cells expressing PPAR $\gamma$ . In contrast,  $\Delta$ 12-prostaglandin J2 has been demonstrated to be made in vivo. A report that estrogen induces the production of  $\Delta$ 12-prostaglandin J2 in duck uropygial gland was interesting in this context, since it could point to an especially interesting dialog between estrogen and peroxisome proliferator-stimulated signaling pathways (122). Other eicosanoids and unsaturated fatty acids are also reported to bind and activate PPAR $\gamma$  (121,123,124). This has been demonstrated for the  $\omega$ -3 polyunsaturated fatty acids,  $\alpha$ -linolenic (18:3), eicosapentaenoic (20:5;EPA), and docohexanoic acid (22:6;DHA) (121,123,124). Two eicosanoids present in oxidized low-density lipoproteins (oxLDL), 9-hydroxyoctadecadienoic and 13-hydroxyoctadecadienoic acid, are also potent PPAR $\gamma$  ligands (125). Finally, an oxidatively modified alkyl phospholipid, hexadecyl azelaoyl phosphatidylcholine (azPC), which is present in the oxLDL particles, has been identified as a high-affinity ligand of PPAR $\gamma$ .

In addition to the above-mentioned natural PPAR $\gamma$  ligands, several classes of synthetic PPAR $\gamma$  agonists have been described (Fig. 5). Most is known about the thiazolidinediones (TZDs), which are potent insulin sensitizers currently used in the treatment of type 2

### Synthetic PPAR $\gamma$ ligands

### Natural PPAR $\gamma$ ligands

**Figure 5** Natural and synthetic PPAR $\gamma$  ligands. Rosiglitazone, troglitazone, pioglitazone, and MCC-555 are members of the thiazolidinedione family of PPAR $\gamma$  ligands, whereas L-tyrosine-based ligands and JTT-501 are not. Rosiglitazone, troglitazone, and pioglitazone have all received market approval, but only rosiglitazone and pioglitazone are actually on the market.

diabetes mellitus (126). L-tyrosine-based PPAR $\gamma$  ligands are another group of promising synthetic PPAR $\gamma$  agonists, which are under development (127). Finally, certain nonsteroidal anti-inflammatory drugs (NSAIDs) (128) were demonstrated to be high-affinity ligands for PPAR $\gamma$ . It is interesting that the relative potency of most TZDs to bind to and to activate PPAR $\gamma$  in vitro seems to correlate with their antidiabetic potency in vivo, suggesting that PPAR $\gamma$  mediates at least in part their antidiabetic effect (126,129). The involvement of PPAR $\gamma$  in insulin sensitization and glucose homeostasis is furthermore supported by the observation that activation of RXR, the heterodimeric partner of PPAR $\gamma$ , also induces a certain degree of adipocyte differentiation and improves glucose homeostasis (130). These observations argue that the active moiety involved in ameliorating glucose metabolism is the heterodimer PPAR $\gamma$ /RXR. More recent work, however, clearly underscores that PPAR $\gamma$  and RXR activation can also have distinct biological effects (131), although a fair number of overlapping effects exists.

Furthermore, the recent observation that synthetic as well as natural PPAR $\gamma$  ligands retain the capacity to exert some modulatory effects in PPAR $\gamma$   $\pm$  macrophages (132,133), points to the fact that certain of these compounds also could have PPAR $\gamma$  independent effects in glucose homeostasis.

Since the current PPAR $\gamma$  agonists are rather weak in monotherapy and because these compounds all have some unwanted side effects (118), there is no doubt that the future will bring another dimension to the development of PPAR $\gamma$  modulators, which until now was focused on the development of simple agonists. First, novel ligands, such as the TZD derivative, KRP-297 and JTT-501, with activity toward both PPAR $\alpha$  and  $\gamma$  are being developed, widening both their tissue-specific activity and pharmacological properties (134,135). Administration of a combination of PPAR $\alpha$  and  $\gamma$  agonists (136) or a single dual-agonist (134), with effects on both liver and adipose tissue, can clearly widen the therapeutic window and enhance their efficacy in complex metabolic disturbances such as insulin resistance

and type 2 diabetes. Although little is known about their pharmacological properties, ligands capable of binding and activating both PPAR $\gamma$  and  $\beta$  have recently been reported (137). These dual PPAR $\gamma$  and  $\beta$  agonists could become highly relevant compounds in the treatment of the many facets of the metabolic syndrome, since they might combine the insulin sensitizing activities of PPAR $\gamma$  activation with the HDL raising activities of PPAR $\beta$  activation.

Second, the discovery of a novel TZD, MCC-555, with significant antidiabetic properties but only weak capacities to bind to PPAR $\gamma$ , makes a notable exception to the rule that PPAR $\gamma$  binding correlates with clinical efficacy (126,129). MCC-555 can function either as a full or partial agonist or as an antagonist pending on cell type and the sequence recognition site. This property can be explained by unique cofactor recruitment by this compound and demonstrates that it will be possible to produce tissue- and promoter-specific PPAR $\gamma$  modulators. Another PPAR $\gamma$  modulator, i.e., FMOC-L-Leucine (FMOC-L-Leu), was recently described in our laboratory (137a). FMOC-L-Leu has some similarity to the tyrosine-based PPAR $\gamma$  ligands but, unlike these last compounds, have a rather weak affinity for PPAR $\gamma$ . Interestingly, two molecules of FMOC-L-Leu bind to the ligand-binding domain of the receptor, as demonstrated by mass spectrometry of the PPAR $\gamma$  ligand-binding domain and FMOC-L-Leu. This unique binding to PPAR $\gamma$  changes the cofactor preference of PPAR $\gamma$ , relative to classical agonist ligands, and results in distinct biological effects characterized by strong insulin sensitization without weight gain.

## VII ADIPOSE TISSUE, TRANSCRIPTION FACTORS, AND FATTY ACIDS IN INSULIN SENSITIVITY

On a whole-body level, adipose tissue is absolutely required for glucose homeostasis. Indeed, subjects with lipoatrophy (138) and transgenic animals that are engineered to lack adipose tissue (76,139) are extremely insulin resistant. This seems therefore to indicate that storage of energy in the adipocytes favors insulin sensitivity and that the important adipogenic activity of PPAR $\gamma$  contributes to the insulin sensitization of PPAR $\gamma$  agonists. Despite the fact that PPAR $\gamma$  seems to have its primary effects on adipose tissue, it is unclear how PPAR $\gamma$  agonists improve insulin sensitivity in muscle. Normally, adipose tissue and liver contribute only minimally to glucose disposal, whereas muscle is

responsible for most of the glucose uptake, yet muscle expresses only trace amounts of PPAR $\gamma$ . This questions whether these minute quantities of PPAR $\gamma$  are sufficient or, alternatively, might be induced during TZD treatment, leading to an eventual direct PPAR $\gamma$ -mediated response of the muscle to these insulin sensitizers. Alternatively, PPAR $\gamma$  activators may generate an adipocyte-derived signal affecting insulin sensitivity in muscle. Both proteins and lipids have been proposed as nonmutually exclusive signaling molecules, which can affect the muscle.

The prototypical examples of protein signaling molecules are the adipocytokines (140). TNF $\alpha$  is the prime example of molecules belonging to this group. Increased adipose tissue TNF $\alpha$  production has been shown to induce systemic insulin resistance by interference with the insulin signaling cascade (111,112). TZDs have been shown to reduce TNF $\alpha$  expression, which may contribute to the improved insulin sensitivity (93,114). More recently, it was demonstrated that also leptin might interfere with insulin signaling in vitro (141–143), although its in vivo activity on glucose homeostasis suggests otherwise (144,145). Two other adipocytokines were recently shown to affect glucose homeostasis—resistin and adipo-Q. Resistin reduces glucose utilization and its expression is decreased by PPAR $\gamma$  activation (116). Although a proteolytically cleaved fragment of adipo-Q improves glucose disposal, it is unknown whether TZDs affect this pathway in vivo (146). Other adipocyte-derived proteins, such as adipsin (147), angiotensinogen (148), and plasminogen activator inhibitor I (140), could also be involved in a similar signaling process, although experimental proof of this is still missing.

A second group of important mediators that affect insulin sensitivity in both muscle and liver and that are derived from adipose tissue, consists of fatty acids. Since the original observation by Randle (149) (reviewed in 150), it has been well established that increased fatty acid concentrations in the muscle decrease glucose metabolism in that tissue (151). Perhaps the most extreme example of fatty acid and triglyceride accumulation in muscle and liver occurs when adipose tissue is completely absent, such as the case in lipoatrophy (152), a condition characterized by extreme insulin resistance (153). In the liver, fatty acids stimulate gluconeogenesis, suggesting that hormonal control of lipolysis in the adipocyte indirectly controls hepatic glucose production (154). This observation is particularly relevant in visceral adipose tissue, which is less sensitive to insulin than subcutaneous fat and which drains directly to the liver via the portal circulation.

Interestingly, treatment with PPAR $\gamma$  activators induces LPL, aP2, FATP-1, and ACS (all genes involved in fatty acid uptake) selectively in adipose tissue, whereas they do not seem to change the expression of these genes in muscle or hepatic tissue (reviewed in 150). This might on a whole-body level induce a "fatty acid steal" due to a specific PPAR $\gamma$ -mediated increase in lipid and fatty acid clearance by adipose tissue, without a concomitant increase in fatty acid delivery to the muscle and liver (155). The resulting "trapping" of fatty acids in fat tissue leads to a decreased systemic availability and a diminished fatty acid uptake by the muscle and liver, potentially improving both muscle insulin sensitivity according to the mechanisms proposed by Randle (149) and hepatic glucose output (154).

From all the above it is clear that the majority of PPAR $\gamma$  regulated genes are involved in fatty acid and/or lipid metabolism and seem to be linked to adipocyte differentiation. In contrast, very little is known about regulation by PPAR $\gamma$  of genes directly involved in glucose homeostasis and insulin signaling. The mRNAs encoding for both the glucose transporter Glut-4 (156) and the insulin receptor substrate 2 (IRS-2) (157) were reported to be induced by PPAR $\gamma$  agonists, although a direct regulation on the promoter activity of the above mentioned genes by PPAR $\gamma$  has not been studied. Similarly, it was demonstrated that the c-Cbl associated protein (CAP) was induced by activation of PPAR $\gamma$  (158). CAP, which is only expressed in cells that are metabolically sensitive to insulin, is involved in insulin-stimulated tyrosine phosphorylation of c-Cbl (158). Upon phosphorylation, the c-Cbl/CAP complex translocates to lipid raft domains of the cell membrane (159) and recruits additional signaling molecules to these lipid rafts, resulting in the activation of the G-protein TC10. This molecular switch provides then a second signal to the Glut-4 protein, parallel to phosphatidylinositol 3-kinase (PI-3K) (159). Also the p85 $\alpha$  subunit of PI-3K was shown to be dose dependently induced by both PPAR $\gamma$  and RXR agonists in isolated human adipocytes, directly proving the implication of the RXR/PPAR $\gamma$  heterodimer in its induction (160). Finally, it is important to stress that other adipose tissue-independent and perhaps PPAR $\gamma$ -independent mechanisms also contribute to the insulin-sensitizing effects of TZDs. In fact, these PPAR $\gamma$  agonists retain some insulin-sensitizing activity in transgenic mice that totally lack adipose tissue (161), and furthermore these agonists have significant anti-inflammatory effects in PPAR $\gamma$ -/- macrophages (132,133). The exact nature of these nonadipose tissue and PPAR $\gamma$ -independent

effects, however, is unclear at present and warrants more detailed investigation.

The extensive cross-regulation among C/EBPs, PPAR $\gamma$ /RXR, and ADD-1/SREBP-1 to induce and sustain adipocyte differentiation suggests that these factors also are of importance in glucose homeostasis (see discussion below). Fasting and feeding regulate ADD-1/SREBP-1c levels via insulin in both fat (162) and liver (163), indicating that ADD-1/SREBP-1c is an intermediate or a target of insulin signaling. SREBP-1c furthermore increases the expression of several genes involved in gluconeogenesis and lipogenesis (74,162–164). Interestingly, hepatic SREBP-1c levels are both increased in a mouse model of lipoatrophy, as well as in the *ob/ob* mouse, a model that reflects the relative leptin deficiency in obesity-induced diabetes (165). Administration of leptin could normalize this effect (145). This led to the suggestion that increased expression of SREBP-1c underlies the mixed insulin resistance/sensitivity, with increased and inappropriate rates of both gluconeogenesis (as a sign of insulin resistance) and lipogenesis (as a sign of insulin sensitivity) (165). A further link between SREBPs and glucose homeostasis is provided by the fact that SREBPs induce the expression of PPAR $\gamma$  (166), and that their lipogenic effects will stimulate the generation of fatty acids ligands for PPAR $\gamma$  (167).

Also the C/EBP family of transcription factors seems to play an important role in glucose homeostasis. Mice homozygous for a mutation in the C/EBP $\alpha$  gene have diminished glycogen stores in the liver and fail to activate gluconeogenic pathways (78,79,168). This leads to premature death of mutant C/EBP $\alpha$  -/- animals postpartum because of severe hypoglycemia (78,79). Defective gluconeogenesis and low glycogen synthase activity was recapitulated in animals in which the C/EBP $\alpha$  gene was disrupted in adult mouse liver with a temporally and spatially controlled strategy using an adenovirus to express the Cre recombinase (169). Also adult C/EBP $\beta$  -/- mice have a significant hypoglycemia after fasting, which is accompanied by lower hepatic glucose output (170). These mice have also a decrease in fasting plasma fatty acid levels (170). All this work suggests that anti-C/EBP strategies could be of value to suppress excessive gluconeogenesis. Whereas these data refer to the effects of C/EBPs on liver glucose homeostasis, there are also some recent data suggesting that C/EBP $\alpha$  is involved in the induction of insulin sensitivity during adipocyte differentiation. Insulin regulation of Glut4 in the adipocytes requires C/EBP $\alpha$ , which is involved in the stimulation of gene expression and tyrosine phosphorylation of the insulin receptor

and the insulin receptor substrate-1 (IRS-1) (77). In view of the extensive cross-regulation between PPAR $\gamma$  and C/EBP $\alpha$ , C/EBP $\alpha$  could be an important indirect target to explain the antidiabetic effects of PPAR $\gamma$  agonists (77). The role of C/EBP $\alpha$  in muscle glucose utilization is less clear.

### VIII GENETIC STUDIES SUPPORT A ROLE OF PPAR $\gamma$ IN ADIPOGENESIS

Approximately 70% of the variance in body mass index (BMI) is genetically determined (171). In this context, the PPAR $\gamma$  gene was also analyzed for mutations. A rare Pro115Gln mutation in the NH<sub>2</sub>-terminal ligand-independent activation domain of PPAR $\gamma$  has been described in four very obese subjects (172). This mutation resulted in a permanently active PPAR $\gamma$  since it inhibited phosphorylation of the protein at Ser114 and led to increased adipocyte differentiation capacity in vitro (172). Furthermore, modification of the A/B domain by phosphorylation of this residue was reported to reduce ligand-binding affinity through interdomain communication between the A/B and the ligand-binding pocket in the DEF domain of PPAR $\gamma$ . Phosphorylation at Ser114 was proposed as a mechanism by which growth factors and insulin, through mitogen-activated protein kinase, decreased PPAR $\gamma$  activity and adipocyte differentiation (173–176).

In addition, a much more common Pro12A1a substitution in the PPAR $\gamma$ 2-specific exon B has been described (177–180). The PPAR $\gamma$ 2 Ala allele, whose frequency ranges from ~0.12 among Caucasians to 0.02 in Japanese-Americans (177,178), was associated with lower BMI, improved insulin sensitivity, and higher plasma HDL cholesterol levels (178). The association with insulin sensitivity disappeared when corrected for BMI, indicating that the primary effect of this mutation was on body weight. Among Japanese-American subjects, a significantly lower frequency of the Ala allele amongst type 2 diabetics was observed relative to normals. The PPAR $\gamma$  Ala allele exhibited a reduced ability to transactivate responsive promoters (178). These observations were confirmed in a very large study, which independently demonstrated that this Pro12A1a mutation was associated with a reduction in BMI and significant insulin sensitization (181). Together with the observations of the Pro115Gln substitution, these results provide strong evidence of a role of PPAR $\gamma$  in the control of adipogenesis in vivo, such that a more active PPAR $\gamma$  (Pro115Gln) results in increased BMI (172), whereas the opposite is seen with

a less active PPAR $\gamma$  (Pro12A1a)(178). Although these studies provide strong evidence for a role of PPAR $\gamma$  in the control of adipogenesis and insulin resistance, some smaller studies in more heterogeneous patient populations found only a weak or no association of the Pro12A1a substitution with BMI and insulin sensitivity (180,182). These apparently conflicting data indicate the importance of gene environment interactions in the determination of the phenotype.

The genetic and functional data on the Pro12A1a substitution point to the importance of the PPAR $\gamma$ 2-specific B exon in determining the activity of PPAR $\gamma$  more particularly in adipocytes, the only tissue known to express significant amounts of PPAR $\gamma$ 2. The exon B-encoded 28 NH<sub>2</sub>-terminal residues were previously shown to be dispensable in in vitro assays of transcriptional activation and adipocyte differentiation (58). In apparent contradiction to this observation, the NH<sub>2</sub>-terminus of PPAR $\gamma$ 2 was shown to be 5–10 times more potent in transactivation assays than the NH<sub>2</sub>-terminus of PPAR $\gamma$ 1 (183). The sequence of the first 13 of these 28 residues in PPAR $\gamma$ 2 is evolutionarily conserved between mouse, pig, cow, and human, indicating that they may be functionally important in vivo (unpublished data) (1). The function of the NH<sub>2</sub>-terminal residues of PPAR $\gamma$ 2 is unknown. This domain may modulate nuclear import, ligand binding, DNA binding, or transcriptional activation by inducing a conformational change, or it may endow PPAR $\gamma$ 2 with unique capacities to interact with coactivators or corepressors that have been shown to interact with nuclear receptors. Support for the role of the NH<sub>2</sub>-terminus of PPAR $\gamma$  in transcriptional activity not only comes from the presence of a ligand-independent AF-1 domain in this part of the molecule (183) but also from its allosteric effects on ligand-dependent transcriptional activity through interdomain communication (184). The identification and characterization of proteins interacting with the NH<sub>2</sub>-terminus of PPAR $\gamma$  in the future will point to mechanisms by which this domain affects adipose tissue accumulation and metabolism.

In combination, these human genetic studies suggested that the major function of PPAR $\gamma$  was fat formation, not insulin sensitization, as was stipulated from pharmacological characterization of the receptor. Additional genetic support for a role of PPAR $\gamma$  in the determination of body fat comes from the fact that one of the loci with suggestive linkage to obesity (LOD = 2.0) in Pima Indians maps close to the location of *PPARG* in the 3p25-p24 region (185). Furthermore, the striking phenotype observed in mice with a mutation in the PPAR $\gamma$  gene confirmed the validity of the human

genetic studies. Whereas homozygous PPAR $\gamma$ <sup>-/-</sup> mice are not viable (most likely due to the complete absence of adipose tissue) (186), heterozygous PPAR $\gamma$ <sup>-/+</sup> mice are characterized by a decrease in adipose tissue mass and, contrary to general expectations, by a marked insulin sensitization (187,188). Although these knock-out (KO) data appear at odds with pharmacological studies with PPAR $\gamma$  agonists, they are fully in line with the above-mentioned human genetic studies on the Pro12A1a and Pro115G1n. In fact, both the human and mouse genetic studies demonstrate that the prime activity of PPAR $\gamma$  is to stimulate adipocyte differentiation and suggest that its effect on insulin sensitivity are associated with the changes in adipose tissue mass. These studies hence also clearly demonstrate an inherent problem of currently marketed PPAR $\gamma$  agonists, which all stimulate PPAR $\gamma$  activity and induce weight gain, a highly undesirable profile in diabetic patients.

## IX PPAR $\gamma$ AND THE CONTROL OF LIPID METABOLISM AND ATHEROSCLEROSIS

In addition to its role in fat storage in the adipocytes, PPAR $\gamma$  is also important in extracellular lipid metabolism, more particularly in that of triglyceride-rich lipoproteins (reviewed in 13,100). Steady-state triglyceride levels are determined on the one hand by their production rates in the liver and gut, a process controlled to a large extent by substrate (fatty acid) availability, and on the other hand by their clearance rate, a process under the control of LPL and apolipoprotein C-III. In fact, activation of either PPAR $\alpha$  and/or PPAR $\gamma$  has pronounced triglyceride-lowering effects, but the mechanisms by which they achieve this are largely different. Whereas TZDs predominantly affect triglyceride clearance, fibrates, which are weak PPAR $\alpha$  ligands, exert their effects both on triglyceride clearance and production rates (reviewed in 13,189). PPAR $\alpha$  activation will reduce the production of apo C-III and triglyceride-rich lipoproteins in the liver (190,191), whereas activation of PPAR $\gamma$  will induce adipose tissue LPL gene expression (99,136), both resulting in a more efficient lipolysis-mediated clearance of triglycerides from the circulation. The induction of the LPL-mediated lipolysis of triglyceride-rich lipoproteins is most likely underlying the increase in LDL particles, often observed after the use of certain TZDs in animal models (such as the *db/db* mouse) or humans with elevated levels of triglyceride-rich lipoproteins (192–195).

Interestingly, the above-discussed genetic studies demonstrated an association between (1) the Pro12A1a substitution in the PPAR $\gamma$ 2 gene and (2) increased HDL cholesterol and reduced total triglycerides levels (178). The genetic association of HDL levels and PPAR $\gamma$ 2 Ala allele suggests that adipose tissue mass has important implications on reverse cholesterol transport (196,197). In addition, these genetic data support a role of adipose tissue in the complex metabolic abnormalities associated with visceral obesity/insulin resistance syndrome, such as elevated triglyceride, small dense LDL, low HDL levels, and increased predisposition to atherosclerosis (198,199). Support for the hypothesis that PPAR $\gamma$  could be involved in certain aspects of the visceral obesity/insulin resistance syndrome, and more particularly in the protection against atherosclerosis, was recently provided both by in vitro (132,133) and in vivo (200,201) studies. Activation of PPAR $\gamma$  could in fact protect against foam cell formation in vitro (132,133), whereas administration of agonists of PPAR $\gamma$  (200,201) or of its heterodimeric partner RXR (201) could reduce atherosclerotic lesions in two different and validated animal models of atherosclerosis.

## X REGULATING PPAR $\gamma$ ACTIVITY THROUGH PROTEIN-PROTEIN INTERACTIONS

A new functional class of proteins, called “cofactors,” was recently shown to play an important role in transcriptional control. Such cofactors also interact with nuclear receptors, and they can either repress (corepressors) or enhance (coactivators) their transcriptional activities (202). Initially, it was thought that cofactors simply bridge transcription factors with the basic transcription machinery, such as in the case of p300, which is also a component of TATA-binding protein complexes (203), or for the p300 homologous protein, CREB (cAMP-responsive binding protein)–binding protein (CBP), which has been shown to be associated with the RNA polymerase II via RNA helicase A (204). Although this bridging function is definitely important, several cofactors also have enzymatic activities, suggesting that they could control gene expression by specifically modifying DNA and chromatin structure. The discovery that several cofactors had either chromatin-remodeling or -modifying activities, which controlled the transition of chromatin from a closed to a more open conformation, and hence affected gene expression, was particularly relevant (Fig. 6).

**Figure 6** Schematic representation of the recruitment of cofactors to the PPAR $\gamma$ /RXR heterodimer. Transcriptional activation of nuclear receptors requires in general the release of corepressor complexes, which contain histone deacetylase activity (HDAC). Coactivators, such as the SRC family members, CBP/p300, pCAF, or the chromatin remodeling SWI/SNF complex, are then recruited to the receptors. These coactivators either facilitate contact of the basal transcription machinery, remodel chromatin, and/or target histone acetyl transferases (HAT) to the promoters of the target genes of the nuclear receptors. The differential docking of cofactors is facilitated by structural changes brought about by ligand binding or receptor phosphorylation.

One group of cofactors, which has ATP-dependent chromatin-remodeling activity, contains a central ATPase that has homology to yeast SWI2/SNF2. The SWI/SNF and related complexes remodel the chromatin structure and hence facilitate the binding of transcription modulators to its DNA binding sites resulting in either stimulation or inhibition of transcription (205–207). Implication of the SWI/SNF chromatin remodeling complex in the transcription mediated by hormone nuclear receptors has so far been shown only for the glucocorticoid receptor (208–210), the estrogen receptor (211), the retinoic acid receptor (212,213), where chromatin remodeling induced by the SWI/SNF complex together with histone acetylation-deacetylation contributes to NR signaling. The modification of PPAR $\gamma$  signaling by chromatin remodeling has not yet been described, although it will most likely be similar to that described for other nuclear receptors. Other proteins involved in the regulation of chromatin structure and function are the family of “high-mobility group” (HMG) chromosomal proteins. HMGI-C belongs to this family of architectural DNA-binding proteins that are abundant, heterogeneous, nonhistone components of chromatin (214). Although they do not have transcriptional activity by themselves, they change the conformation of DNA and may hence influence transcription. Support for the involvement of HMGI-C in

adipogenesis is provided by the observation that the mouse mutant *pygmy*, characterized by its small size and disproportionally reduced body fat content, was found to be a null allele of HMGI-C (215). Further evidence comes from the finding that in certain lipomas gene rearrangements were found in which the HMGI-C DNA-binding domain was fused to either a LIM or an acidic transactivation domain (216,217). In the first case, the LIM domain of the translocation partner could recruit transcriptional activators to the DNA site, whereas in the second case, the fusion of the HMGI-C protein to an acidic transactivation domain could turn the chimeric protein into a powerful transcriptional activator. Thus, the lack or reduced expression of HMGI-C could predispose to leanness, whereas the juxtaposition of its DNA-binding motif to transcriptional regulatory domains could promote adipogenesis. Furthermore, transgenic mice carrying a truncated HMGI-C gene, which contains only the AT hook domains, develop a giant phenotype and abdominal and pelvic lipomatosis (218). In addition to its role in regulating chromatin structure during adipogenesis, it has been shown that another member of the HMG i.e., HMG(Y), mediates adipocyte differentiation by physically interacting with C/EBP $\beta$ , enhancing its transcriptional activity (219).

Members of three groups of coactivators—the p160 steroid receptor coactivator family (SRC); CBP/p300, the p300/CBP associated factor (p/CAF)/GCN family; and the nuclear receptor coactivator ACTR—have been reported to acetylate histones (220–225) as well as other proteins of the transcription complex, such as TFIIE $\beta$  and TFIIF (226). In contrast, corepressors such as the silencing mediator for retinoid and thyroid hormone receptors (SMRT) and nuclear receptor corepressor (NCoR) occur in complexes which show histone deacetylase activity (227–229). Histone hypoacetylation is associated with transcriptionally silent and condensed nucleosomes, whereas acetylation is associated with increased transcription, suggesting that alterations of nucleosome conformation modulate accessibility of promoter regions. Regulation of the acetylation of histones and of other DNA binding proteins seems therefore to be of prime importance for transcriptional activation, which often occurs as a multistep process involving first removal of histone deacetylases (HDACs) from DNA with subsequent recruitment of histone acetyl transferases (HATs) (Fig. 5). In general, unactivated nuclear receptors are complexed with corepressors, which extinguish their transcriptional activity by the recruitment of HDACs. Activation of the receptor induces then a conformational change

which results in the dissociation of corepressors and the recruitment of coactivator complexes that contain proteins with HAT activity, which facilitates target gene transcription (for review, see 230). A further issue of discussion is how the different groups of cofactors mentioned above interface in controlling the transcription of PPAR $\gamma$  target genes.

An important number of putative cofactors interact with PPAR $\gamma$ , but a firm role in the regulation of the transcriptional activity of PPAR $\gamma$  has not always been established. In the section below we will specifically focus on cofactors for PPAR $\gamma$ , which have been shown not only to bind to but also to modulate its transcriptional activity. SMRT is a corepressor that inhibits retinoic acid receptor and thyroid hormone receptor-dependent transcription in absence of their respective ligands and targets HDACs to the DNA (231,232). In presence of ligands, SMRT dissociates from these receptors allowing the recruitment of coactivators. Lavinsky et al. suggested that SMRT may also be involved in down-modulating PPAR $\gamma$ -mediated gene transcription (233). Indeed, EGF enhances the interaction of PPAR $\gamma$  and SMRT in whole-cell extracts from CV-1 cells. Furthermore, antibodies directed against SMRT can relieve the MAP kinase-dependent inhibition of the PPAR $\gamma$  transcriptional activity (233). Interestingly, microinjection of antibodies directed against SMRT could relieve SMRT corepression of PPAR's activity, whereas antibodies directed related NCoR were ineffective (233). However, these data seem at odds with the observation that PPAR $\gamma$  seems only to be capable to interact with SMRT and N-CoR in solution, but not when bound as a heterodimer with RXR to its cognate response element (45,234). Furthermore, PPARs seem to be lacking the conserved CoR box (45), previously determined to be required for binding of corepressors to the receptors. These conflicting data sets therefore leave the question open, whether unliganded PPAR $\gamma$  has any constitutive repressive activity on gene expression *in vivo*.

Members of at least two families of histone acetylases, CBP/p300 and the SRC family, are reported to interact with PPAR $\gamma$ . CBP and p300 are two related and widely expressed (235) cofactors that were originally identified as CREB (236) and E1A (237) interacting factors (for review see 238). CBP/p300 coactivates numerous transcription factors including several nuclear receptors (239–244), and was reported to have intrinsic HAT activity (220,223,225). We have observed that CBP/p300 interacts with PPAR $\gamma$  through multiple domains in each protein (245). Most notably, the NH<sub>2</sub>-terminal region of PPAR $\gamma$  can dimerize with CBP/p300 in absence of ligand, and this association

enhances its constitutive AF-1 transcriptional activity (245). The constitutive presence of cofactors such as CBP/p300 could hence enhance the basal ligand-independent transcriptional activity of PPAR $\gamma$  *in vivo* and could together with the absence of well-documented interactions with corepressors explain the high level of basal activity of PPAR $\gamma$ . A last point worth noting is that CBP/p300 seems to be able to contact other cofactors, such as SRC-1 and its related family members (246). This suggests that CBP/p300 could facilitate the assembly of multiprotein complexes involved in gene activation.

The SRC family of cofactors is also of notable interest for PPAR $\gamma$ . SRC-1 was initially isolated as a progesterone receptor (PR) coactivator (247) but has since also been shown to interact in a yeast two-hybrid system with the PPAR $\gamma$  LBD (248). Like CBP/p300, SRC-1 has an intrinsic HAT activity (224) and is ubiquitously expressed (235,247). SRC-1 has a lower affinity for PPAR $\gamma$  than to CBP/p300 (249). SRC-1 has been shown to have two PPAR binding domains, each containing the LXXLL consensus receptor interaction motifs (23,250). However, also some residues COOH-terminal to the LXXLL motifs are involved in receptor interaction (251). The liganded PPAR $\gamma$  LBD has been cocrystallized with a region of SRC-1 that contains two LXXLL motifs (15). The structural data reveal that the SRC-1 fragment interacted with two PPAR $\gamma$  LBDs, with each of its LXXLL motifs contacting conserved residues in H12 (contains the AF-2) and H3 (15). Mutation of the AF-2 is associated with a loss in transcriptional activity and a loss of the capacity to interact with SRC-1 or CBP (249). Also other related members of the SRC family of cofactors, such as Tif2/Grip1 and ACTR/RAC3/AIB/pCIP, have been shown to interact with PPAR $\gamma$  in a manner similar to SRC-1. One interesting issue related to this family of cofactors, which requires further investigation, is whether these different SRC family members are recruited specifically by different PPAR $\gamma$  ligands and whether these different SRC family members exert distinct effects on transcription of target genes and would in consequence have different biological activity. Our comparative studies with rosiglitazone and FMOC-L-Leu, discussed above, would suggest that such a ligand-specific differential cofactor recruitment is in fact possible (137a).

Since both p300/CBP and SRC family of cofactors are not specific for PPAR $\gamma$ , several labs have tried to identify PPAR $\gamma$ -specific coactivators. Two coactivators, PPAR-binding protein (PBP) (252) and PPAR gamma coactivator-1 (PGC-1) (253), were isolated using this approach, but they turned out later not to be specific for PPAR $\gamma$ . In addition, and in contrast to

CBP/p300 and the SRC-1 families, it is not established whether these proteins contain any HAT activity. The first of these proteins isolated on the basis of its interaction with the LBD of PPAR $\gamma$  in a yeast two-hybrid screen of a mouse liver cDNA library is PBP (252). PPAR $\gamma$  and PBP are constitutively associated both in vitro and in vivo, but the presence of a ligand reinforces this interaction. PBP stimulates PPAR $\gamma$  transcriptional activity only modestly but a truncated form bearing only the receptor-binding domain acts as a dominant-negative repressor, suggesting that PBP is a genuine coactivator for PPAR $\gamma$ . PBP is expressed in a wide range of tissues, including several tissues where PPAR $\gamma$  is of physiological importance, such as adipose tissue, colon, and breast (254).

PBP has been shown to be identical to TRAP 220 (255) and DRIP 205 (256), two proteins that were isolated as part of a multiprotein complex interacting in a ligand-dependent fashion with the thyroid and vitamin D receptor, respectively. The TRAP/DRIP complexes were subsequently reported to be similar to the activator-recruited cofactor (ARC)(257) and Srb/Mediator coactivator (SMCC)(258) complexes. The TRAP/DRIP/ARC/SMCC complex lacks CBP/p300 or SRC proteins and is recruited to the AF-2 domain via a single LXXLL motif of TRAP 220/DRIP 205 (259,260). Interestingly, the TRAP/DRIP/ARC/SMCC complex is absolutely required for transcriptional activation by nuclear receptors in cell-free in vitro transcription assay (255,256) and on chromatin-organized templates (259). Evidence that this complex might also be involved in PPAR $\gamma$  signaling and adipogenesis came from the observation that cells derived from the PBP  $-/-$  animals had a decreased capacity for ligand dependent activation of PPAR $\gamma$  (261). Furthermore, the phenotype of the KO animals for TRAP 220 and PBP shared some features with the PPAR $\gamma$   $-/-$  mice in that the TRAP 220  $-/-$  animals, were small and have heart defects (262), whereas the PBP  $-/-$  animals have a defect in placenta formation (261). Further exploration as to whether adipogenesis is defective is required to unequivocally establish a role of PBP in PPAR $\gamma$  signaling.

The coactivator PGC-1 was isolated in a yeast two-hybrid screen of a mouse brown fat cell cDNA library (253). PGC-1 again turned out to be not specific for PPAR $\gamma$ , since it also interacts with other receptors such as PPAR $\alpha$ , TR, and a set of mitochondrial transcription factors (253,263,264). Interestingly, the interaction between PGC-1 on the one hand and PPAR $\gamma$  and PPAR $\alpha$  on the other hand is ligand independent both in vitro and in vivo and seems independent of the LXXLL motif. This LXXLL motif is, however, involved in the ligand-dependent interaction of PGC-1

and other nuclear receptors, such as the estrogen and glucocorticoid receptors (265,266). In addition, PGC-1 seems in its turn to interact with both SRC-1 and CBP/p300, leading to a model in which interaction of PGC-1 with PPAR $\gamma$  stimulates recruitment of the SRC-1 and CBP/p300 coactivators (267). PGC-1 is expressed in brown fat, heart, kidney, and brain, all tissues in which PPAR $\gamma$  might be of physiological importance, and its expression is induced upon cold exposure in brown fat and skeletal muscle. When PGC-1 is ectopically expressed in white adipose cells, PGC-1 activates expression of the uncoupling protein (UCP)-1, a key mitochondrial enzyme of the respiratory chain, normally restricted in expression to brown adipose tissue (253,263). PGC-1 has been shown to activate the nuclear respiratory factor 1 (NRF-1), a transcription factor that regulates genes in mitochondrial DNA replication and transcription, stimulating in this way mitochondrial biogenesis (263).

In addition, PGC-1 contributes to the induction of genes important for the oxidative phosphorylation pathway in the mitochondria, such as the genes for cytochrome c oxidase subunits II and IV, and ATP synthetase in muscle and fat cells (253,263). These observations suggest that PGC-1 could play a role in linking nuclear receptors to adaptive thermogenesis and indicate that it could be involved in the initiation of brown adipose tissue formation. Recently, PGC-1 has been demonstrated to regulate also certain aspects of glucose homeostasis. In fact, PGC-1 expression restores Glut4 levels in myoblast cell liner (268). This effect is mediated in part through activation of the muscle-specific transcription factor MEF2C (268). Finally, it was recently demonstrated that PGC-1 is not only involved in transcriptional induction of gene expression, but also in posttranscriptional aspects of gene regulation such as in mRNA processing (269). This mRNA processing activity is the result of a direct association of PGC-1 with splicing factors and other components of the polymerase II elongation and mRNA processing complex.

From the above it is evident that although several cofactors interact with PPAR $\gamma$ , none of these cofactors seem to be specific for PPAR $\gamma$ . Understanding how these cofactor complexes interact and modulate receptor activity will require detailed structural studies, careful reconstitution of PPAR $\gamma$  transcriptional activity in purified reconstituted transcription systems, and a detailed characterization of their biological implication in vivo in animal model systems. Furthermore, several cofactors seem to be interacting as multiprotein complexes, suggesting a certain degree of redundancy. The mode of action of the receptor interacting protein 140

(RIP140) suggests that some of them are mutually exclusive when interacting with the same receptor (270), pointing to the importance of the stoichiometry of the different components in the transcription complexes. Therefore it will also be of interest in the future to better characterize the expression profiles of the various cofactors as well as to get more insight into the regulation of their respective promoters.

## XI CONCLUSIONS AND PERSPECTIVES

Although PPAR $\gamma$  is today one of the best-characterized nuclear receptors, there are still enormous challenges ahead of us before the complex function of this transcription factor in the control of adipogenesis will be unraveled. In view of the fact that PPAR $\gamma$  represents an important therapeutic target for the treatment of insulin resistance and type 2 diabetes, a careful understanding of its exact role in physiology is an absolute requirement. This implies a detailed knowledge of all activities of PPAR $\gamma$ , which are much broader than a strict function in adipose tissue. Most important, perhaps, is our need to understand the role of PPAR $\gamma$  in the control of cell proliferation and differentiation. In addition, we need to identify novel ways to modulate PPAR $\gamma$  activity, without inducing unwanted side effects, such as the potential to enhance macrophage foam cell formation (6,125,271), stimulate colon carcinogenesis (272,273), and induce acute liver dysfunction (274). This will require thorough understanding about how this receptor interacts with cofactors and how it activates transcription. Furthermore, the restricted expression of certain PPAR $\gamma$  isoforms, such as the adipose-restricted PPAR $\gamma$ 2 form, suggests the feasibility of the development of PPAR $\gamma$  modulators affecting only one specific tissue, such as adipose tissue. All these developments will undoubtedly facilitate the more rational design of new classes of PPAR $\gamma$  modulators, which might not be restricted to agonists, but might also include antagonists or inverse agonists, which could also have interesting therapeutic applications beyond the treatment of metabolic diseases.

## ACKNOWLEDGMENTS

We thank Laurent Gelman and Jean-Paul Renaud for help with the cofactor and structural sections, respectively. The members of the "Auwerx" lab are acknowledged for support and discussions. Actual work in the laboratory of the authors is supported by grants of

CNRS, INSERM, CHU de Strasbourg, ARC (contract 9943), the Juvenile Diabetes Foundation (1-1999-819), the European community RTD program (QLG1-CT-1999-00674), Ligue Nationale Contre le Cancer, and the Human Frontier Science Program (RG0041/1999-M). L.F. is a research associate of INSERM, and J.A. is a research director with CNRS.

### I INTRODUCTION

#### A Visceral Obesity and Health—A Brief Historical Perspective

In humans and other mammals, fat is deposited within anatomically discrete depots that are located throughout the body. In humans, while most fat is present in subcutaneous depots, up to 20% of total body fat is deposited in adipose depots within the abdominal cavity (see Table 1). The pattern of fat distribution is a main determinant of variations in body shape (1–3). Vague first noted that that an upper body (android or male-type) fat distribution is associated with development of diabetes, atherosclerosis, and gout (4,5). Kissebah et al. (6,7) and Krotkiewski et al. (6), among others, confirmed and extended Vague's hypothesis, finding evidence for correlations of upper-body obesity and enlarged abdominal subcutaneous fat cells to hypertension, insulin resistance, and hyperlipidemia in clinical studies. Epidemiological studies showed that upper-body fat distribution, measured by the ratio of waist to hip circumferences, was a significant determinant of diabetes, cardiovascular disease, and premature death in both men and women (3). These statistical associations were independent of overall obesity, as assessed by the body mass index. Thus, much research

attention became focused on the phenomenon of abdominal obesity.

With the application of imaging technology to the study of fat distribution, it became possible to better define fat distribution by distinguishing the relative sizes of intra-abdominal and subcutaneous fat compartments. It was realized that increased waist circumference was a heterogeneous phenotype associated in some cases with high amounts of intra-abdominal fat, and in others with mostly subcutaneous abdominal fat. Many studies found that the size of intra-abdominal fat stores as measured by computerized tomography (CT) or magnetic resonance imaging (MRI) was most closely linked with the metabolic complications of obesity (1,7–9).

#### B The Portal Hypothesis

The statistical association between abdominal obesity and health risk does not prove a causal relationship (10). Thus, investigators addressed potential mechanistic links between the size of specific fat depots and alterations in systemic metabolism. As noted by Björntorp (10), there was accumulating evidence in the literature from 1960s and 1970s that fat cells from different fat depots exhibit marked differences in functional capaci-

**Table 1** Major Fat Depots in Humans and Rodents**Humans**

- I. Intra-abdominal or visceral<sup>a</sup> adipose tissue depots
  - A. Intraperitoneal
    1. omental—greater and lesser
    2. mesenteric—small intestine, colon-rectum, epiploic
    3. umbilical/round/falciform ligament
  - B. Extraperitoneal (including pre- or properitoneal)
    1. perirenal<sup>b</sup>
    2. peripancreatic<sup>b</sup>
    3. urogenital (bladder, uterus, prostate)
- II. Subcutaneous fat depots (deep and superficial compartments)
  - A. Truncal (anterior or posterior chest)
  - B. Mammary (only one compartment)
  - C. Abdominal
  - D. Lumbar
  - E. Gluteal
  - F. Femoral

**Rodents**

- I. Intra-abdominal
  - A. Mesenteric
  - B. Omental
  - C. Gonadal (parametrial or epididymal)
  - D. Perirenal (“retroperitoneal”)
- II. Subcutaneous
  - A. Truncal
    1. cervical<sup>b</sup>
    2. axillary<sup>b</sup>
    3. interscapular<sup>c</sup>
    4. dorsal
  - B. Inguinal

<sup>a</sup> Operationally defined as “intra-abdominal” on CT or MRI images.

<sup>b</sup> Contains some brown adipose tissue.

<sup>c</sup> Mainly brown adipose tissue.

ties and responsiveness to nutritional manipulations (11). In particular, a consistent finding was that omental fat cells were more lipolytically active than subcutaneous ones (12–14). Because the omental (and mesenteric) fat depots drained their venous blood into the portal vein, it was hypothesized that these ‘portal’ adipose tissues would be the most metabolically dangerous by virtue of the impact of high levels of lipolytic products on hepatic metabolism. Indeed, evidence that fatty acids caused deleterious effects on hepatic metabolism, including decreased insulin degradation, impaired insulin sensitivity, and increased VLDL output, fueled acceptance of the ‘portal hypothesis’ of Björntorp (15). However, in part because of the difficulty of directly measuring portal concentrations of fatty acids, there is no clear evidence that the high in vitro lipolytic rates of portal adipose tissues are translated into high in

vivo activity and therefore high portal fatty acid delivery in humans (16,17). Some animal data do support the possibility that an increased mass of visceral adipose tissues lead to increased portal fatty acids levels in vivo (18–20).

## C Extending the Portal Hypothesis

Recent evidence that adipose tissues are also heterogeneous in their endocrine functions raises the possibility for additional mechanistic links between visceral adiposity and metabolic derangements (18,21). A growing body of literature indicates that there are marked differences in the secretory products of visceral and subcutaneous adipose tissues, including leptin, interleukin-6, plasminogen activator inhibitor-1, and adiponectin, that may contribute to the development of the metabolic syndrome (21,22).

## D Goals of this Chapter

The size of intra-abdominal fat stores, as determined by CT, is strongly influenced by genetic factors, and the genes associated with intra-abdominal fatness are different from those determining overall obesity (23). Thus, visceral fat appears to represent a subset or type of adipose tissue that has distinct determinants and metabolic characteristics. The main goals of this chapter are to define ‘visceral fat’ from a biologic and clinical perspective and to review our knowledge of its cellular composition and its metabolic and endocrine properties, focusing mainly on data in humans. We will also discuss physiologic determinants of the size of visceral fat depots and the influence of therapeutic interventions on visceral adiposity.

## II DEFINITION, ANATOMICAL DESCRIPTION, AND MEASUREMENT OF VISCERAL ADIPOSE TISSUE

It is now well established that CT and MRI are the preferred methods for measuring visceral adipose tissue (VAT) in vivo and that the two methods provide images of the abdomen that are comparable and that are characterized by good tissue contrast (for further details see the chapter by Heymsfield et al.) However, despite evidence that CT (24) and MRI (25) provide accurate estimates of VAT by comparison to cadaver sections, the best way to apply these methods to the measurement of VAT in vivo is not firmly established. Thus several issues require clarification.

**Figure 1** Axial computerized tomography (CT) and magnetic resonance imaging (MRI) images obtained in the midabdomen. Adipose tissue appears black on the CT image and white on the MRI image. VAT, visceral adipose tissue; ASAT, abdominal subcutaneous adipose tissue.

### A Visceral Adipose Tissue Defined

Despite the acknowledged importance of VAT in the etiology of metabolic risk (7,26), there is no consensus as to the ideal protocol for measuring VAT in research settings. Anatomically defined VAT is that contained within the visceral peritoneum (i.e., omental and mesenteric). The visceral peritoneum is the membrane that covers, with few exceptions, the abdominal organs of the gastrointestinal tract. This definition excludes retroperitoneal adipose tissue, which, from a clinical point of view, is reasonable, given the hypothetical role of free fatty acids liberated from omental and mesenteric adipose tissue in the etiology of metabolic risk, the so-called portal theory (15). However, because the peritoneum is not visible on either CT or MRI images, separation of VAT into intraperitoneal (omental and mesenteric) and retroperitoneal (i.e., perirenal) components, has relied on arbitrary criteria (27,28). Accordingly, efforts to determine whether separation of VAT into intraperitoneal and retroperitoneal provides additional insight into the relationship between the VAT depot and metabolic risk provide equivocal results (29–33). However, at present the weighted evidence from clinical studies appears to suggest that subdivision of VAT into intraperitoneal and retroperitoneal depots is not warranted and thus, in practice, VAT on CT and MRI axial images within the abdomen region includes all visible intra-abdominal adipose tissue (Fig. 1). However, as discussed in Section IV, there is heterogeneity

in the functional properties of the intraperitoneal and retroperitoneal fat depots of humans that may be relevant to understanding the relationships between so-called visceral adiposity and metabolic disease.

As illustrated in Figure 2, it is clear from a coronal perspective that VAT deposition extends throughout the abdominal region. Moreover, it is well established that the accumulation of VAT differs according the level of the abdomen at which the CT or MRI image is

**Figure 2** Visceral adipose tissue depicted by magnetic resonance imaging in the coronal plane.

obtained (34–37) (Fig. 3). However, as illustrated in Figure 3, the relative difference between those with high and low VAT is relatively homogeneous throughout the abdomen. This may partially explain why the relationship between VAT and metabolic risk factors is not influenced by the level of the abdomen at which VAT is measured (31,36). Thus, while a universally accepted definition of VAT awaits resolution, it would appear that the ability to determine individual health risk, as conveyed by the accumulation of VAT, can be determined by a single MRI or CT image of the abdomen. This is generally true for axial images acquired in a region of the abdomen bordered by S1-L5 and L1-T12 (31,34,38).

To summarize, human VAT for practical reasons includes all visible intra-abdominal adipose tissue on CT or MRI images. Although the anatomical landmarks that define VAT are not yet established, evidence suggests that the relationship between VAT and metabolic risk factors appears to be similar independent of the level of the abdomen at which VAT is measured; thus, observations from images obtained at different levels of the abdomen are comparable.

It should also be noted that subcutaneous fat can be divided into deep versus superficial subcutaneous fat layers) that are observable on CT images above and below Scarpa's fascia (fascia superficialis). The volume of the deep abdominal subcutaneous fat layer is independently associated with insulin resistance and dyslipidemia (36,39). As most studies do not distinguish subcompartments of subcutaneous fat, these findings

**Figure 3** Visceral adipose tissue at the L4-L5 level, 5 cm below, 5 cm above, 10 cm above, and 15 cm above L4-L5 in 91 Caucasian men with low visceral adipose tissue ( $<125 \text{ cm}^2$  at L4-L5) and 110 Caucasian men with high visceral adipose tissue ( $>125 \text{ cm}^2$  at L4-L5). The numbers represent the relative difference between the high and low visceral adipose tissue groups for each of the five abdominal images.

may explain some discrepancies in the literature on the contribution of VAT to metabolic complications.

## B VAT in Rodent Models

Intra-abdominal fat depots of rats include the perirenal, retroperitoneal, gonadal, and mesenteric and omental (40) (note that in rodents, the so-called retroperitoneal fat depot is not outside the peritoneal cavity). Of these, only the mesenteric depot is associated with the digestive tract, is substantial in size, and drains portally. The omental fat depot in rodents, in contrast to that in humans, is much smaller than mesenteric and not usually dissected or studied. Thus, the mesenteric depot of rodents would probably be the best “model” of a human (visceral)portal depot. Data from Warden (41) indicate that genes that determine the size of mesenteric depot are distinct from those regulating the size of other depots, supporting the contention that this visceral fat depot is anatomically and probably metabolically distinct.

The relative distribution of fat appears to differ in humans and rats because the latter deposits relatively more total fat within intra-abdominal depots. Over 50% of the total fat mass of rats is accounted for by intraabdominal fat (42). In contrast, in humans the total intra-abdominal (including omental and mesenteric) fat mass is only  $\sim 20\%$  of the total (most is subcutaneous). Furthermore, whereas in humans the size of subcutaneous fat cells are as large as or larger than intra-abdominal ones, in rats subcutaneous fat cells tend to be smaller than those from intra-abdominal depots such as epididymal or retroperitoneal (40,42,43). Thus, the metabolic effects of removal of intra-abdominal fat depots should not be assumed to be comparable to the removal of the “portal” adipose tissues. Caution should be used in extrapolating data about the metabolic effects of altered fat distribution in rodent models to the human (e.g., 44).

## III DESCRIPTIVE CHARACTERISTICS—EFFECTS OF GENDER, RACE

### A Gender

It is generally reported that, for a given BMI (38) or body fat (45), the accumulation of VAT is lower in women than in men. Lemieux et al. (45) studied a cohort of 89 men and 74 premenopausal women varying in total and visceral adiposity. In that study, the authors report that men have significantly greater quantities of VAT than women after correction for differences in

total adiposity. Because VAT is a strong correlate of metabolic risk (7,26), these observations may partially explain the greater obesity-related health risk that characterize men by comparison to obesity-matched women. This notion is reinforced by Couillard et al. (46), who report that the well established gender dimorphism in postprandial triglyceride response (women less than men) is eliminated when men and women are matched for VAT accumulation.

The relative masses of deep vs. superficial subcutaneous fat also varies by gender and because this covaries with VAT volume, this may factor into metabolic risk (36,39). Men have relatively more deep than superficial SAT (36) than women. However, type 2 diabetic men have less superficial but similar amounts of deep SAT as women (47).

## B Race

It is generally reported that African-American men and women have less VAT than Caucasian men and women (36,48–50). The race differences in men remain after statistical control for differences in total adiposity (36,48). However, in women the racial dimorphism between African-American women and Caucasian women disappears after control for variation in total adiposity (36,48). However, Albu found that after adjusting for total fat, black women had less VAT and VAT/SCAT for any waist-to-hip ratio (50). This racial difference in VAT accumulation is apparent in childhood as it is commonly reported that African-American children have less VAT by comparison to age-matched Caucasian-American children (51,52). This clinical or metabolic importance of VAT accumulation in children is unclear. Goran et al. (51) report that in both African-American and Caucasian children insulin sensitivity is more closely related to total body fat than to VAT. This may not be surprising given that in children the vast majority of VAT is located posterior to the peritoneum (i.e., is not portally drained). Thus, if the “portal theory” (15) is the mechanism that links VAT and metabolic risk, given the relatively small accumulation of omental and mesenteric fat (Fig. 4) in children, one would not expect VAT to be a strong marker of metabolic risk in children.

Apart from comparisons of African-American with Caucasian men and women, it has recently been reported that healthy Asian-American women have greater quantities of VAT than European-American women after adjustment for differences in total adiposity and age (53). However, no differences in VAT accumulation were observed after control for differ-

**Figure 4** Magnetic resonance image obtained at the level of the umbilicus in a 12-year-old girl.

ences in age and total adiposity in Asian-American men by comparison to their European-American counterparts.

## IV COMPOSITION OF VISCERAL FAT DEPOTS

### A Types of Cells Within Visceral and Subcutaneous Fat Depots

All fat depots contain adipocytes, preadipocytes, endothelial cells, mast cells, and fibroblasts. There are no systematic studies that characterize and quantify the different cell types present in visceral compared to subcutaneous fat. The omental fat depot is also rich in mesothelial cells, apparently derived from the peritoneum (54–56).

There appear to be more macrophages present in omental than subcutaneous adipose tissue (57). The abundance of lymph nodes in visceral depots may also be of importance in determining the metabolic activity of surrounding adipocytes (58).

The number of preadipocytes in omental fat may be lower than in subcutaneous (59). Because nonadipose cells including preadipocytes produce many cytokines including tumor necrosis factor- $\alpha$  (60) and interleukin-6 (61,62) and other proteins that may influence adipocyte metabolism, it seems likely that the paracrine environment of different depots differs between visceral and subcutaneous fat, at least in part, by virtue of the different cell types present. These differences in cellular composition may underlie regional differences in adipocyte metabolism, and hence variations in the regional deposition of fat or its function.

## **B Size of Visceral Adipocytes**

In lean men and women, omental fat cells are smaller than subcutaneous ones (63–66). In obese men, most studies indicate that omental fat cells are similar in size to subcutaneous (66–69). In obese women, however, omental fat cells are ~20–30% smaller (68–70). Variations among studies are probably due to the relatively small number of subjects studied in each (usually 10–20) and random variations in fat distribution that may add to variability. Some studies also pool small numbers of women and men. Mesenteric fat cells of severely obese individuals are reported in several studies to be larger than omental (70), most markedly in men (68,69). However, some studies (67) find no difference between omental and mesenteric adipocytes. Round ligament adipocytes tend to be larger than omental, mesenteric, or subcutaneous (71,72).

## **V METABOLIC CHARACTERISTICS OF VISCERAL ADIPOSE TISSUE**

Increased catecholamine sensitivity and lower insulin sensitivity may contribute to higher turnover of fatty acids (FA) in visceral versus subcutaneous adipocytes. Most studies of lipolysis in visceral adipose tissue have studied omental fat cells (12). Limited data indicate that omental and mesenteric adipocytes behave similarly, with only minor, gender-specific differences detected in some studies (65,67,73). Adipocytes from the round ligament appear to be markedly different (72).

### **A Basal Lipolysis Is Lower in Omental Than in Subcutaneous Fat Cells**

Most studies indicate that adipocytes isolated from the omental depot of lean or obese men and women exhibit lower basal lipolysis, even when the rates are corrected for cell size (surface area) (12,70,72,74). Similar results are obtained when basal lipolysis is assessed in the absence or presence of adenosine deaminase (ADA) to permit maximally disinhibited lipolysis (12,74). However, when high concentrations of fat cells were incubated in the absence of ADA, no differences in basal lipolysis were detectable (65,75). The low rates of basal lipolysis under these conditions may make it difficult to detect differences. Indeed, omental fat cells are reportedly less sensitive to adenosine inhibition of lipolysis (76). Similarly, studies of intact fragments of adipose tissue from obese subjects revealed no difference in basal lipolysis in men, but did show a clearly lower lipolytic

rate in women (77). Thus, it is possible that there may be gender-specific differences in the sensitivity of omental adipocytes to paracrine regulators. Overall, available data indicate that omental adipocytes exhibit lower basal lipolytic capacity. The higher expression of the constitutively active endothelial nitric oxide synthetase (eNOS) in omental fat has been implicated in its lower basal lipolysis (78).

### **B Sensitivity and Responsiveness to Lipolytic Agonists Are Greater in Visceral Fat**

Maximally beta-adrenergic-stimulated rates of lipolysis by a nonspecific agonist are similar in omental and subcutaneous adipose tissues (72,73). Because of the lower basal, the increment ( $\Delta$ ) over basal is higher in omental than in subcutaneous. Mesenteric fat cells appear to also exhibit increased responsiveness to isoproterenol, particularly in men (73). Omental fat cells exhibit about twofold higher responses to physiologic catecholamines that activate both beta (stimulatory) and  $\alpha_2$ - (inhibitory) adrenergic receptors (66). Only minor but statistically higher responses to  $\beta_1$ -adrenergic receptors occur in omental than in subcutaneous fat cells of lean men (66). However, there are impressive differences in the sensitivity of omental fat cells to adrenergic receptor subtypes. Omental fat cells of obese men exhibit markedly increased sensitivity ( $ED_{50}$ ) as well as increased responsiveness to beta-adrenergic agonists, particularly to the  $\beta_3$  agonist CGP 12177 and decreased responsiveness to the antilipolytic effects of  $\alpha_2$ -adrenergic receptors (66,72,79,80). Omental fat cells of men as compared to women are markedly more sensitive to the lipolytic effects of beta-adrenergic agonist, particularly the  $\beta_3$  component (79).

The differences in beta-adrenergic responsiveness between omental and subcutaneous fat cells appear to derive from alterations in receptor expression rather than postreceptor events (74). No differences in  $G_i$  or  $G_s$  subtypes (76) are reported. Levels of HSL expression (protein and mRNA) are reported to be lower in omental than in subcutaneous (SC), predicting the lower maximal rates of lipolysis in omental that were in fact observed in some studies (64).

### **C Antilipolytic Effect of Insulin Is Lower in Omental Than in Subcutaneous Adipocytes**

Studies are consistent in reporting a decreased sensitivity and responsiveness to the antilipolytic effect of insulin in omental compared to fat cells. The  $ED_{50}$  for

insulin antilipolysis is higher in omental (71,81). Zierath et al. reported that insulin was two- to fourfold less potent in stimulating insulin receptor autophosphorylation and IRS-1 phosphorylation times in omental than in subcutaneous adipocytes. IRS1 protein expression was only half that in omental than SC. In parallel with these alterations in insulin signaling, insulin was less effective in suppressing lipolysis and increasing FA reesterification in omental adipocytes (81). These *in vitro* results are consistent with the reports that splanchnic lipolysis is less suppressible by insulin *in vivo* (82).

#### **D Is Lipolysis in Visceral Fat Increased *In Vivo*?**

The rate of lipolysis *in vivo* depends on the balance of lipolytic and antilipolytic regulators. For example, the rise in catecholamines with fasting is coupled with a lowering of circulating insulin levels. Because catecholamines sensitivity is markedly greater and insulin sensitivity is lower in omental than in subcutaneous fat, the *in vitro* studies would predict higher rates of lipolysis. In the fed state (high insulin, low catecholamines), determinants of "basal" lipolysis as well as insulin sensitivity likely factor into the rate of lipolysis, and it is therefore difficult to predict. *In vivo* studies reveal that under hyperinsulinemic conditions, the contribution of visceral (splanchnic) lipolysis to total systemic lipolysis increased from ~10% to 40%, suggesting the physiologic importance of the lower insulin sensitivity of omental adipocytes (82). Nevertheless, *in vivo* studies appear to indicate that non-splanchnic, upper body subcutaneous fat depots make a larger contribution to hepatic FFA delivery than visceral fat (83). Surprisingly, in subjects with NIDDM in whom visceral fat depots were enlarged, the relative contribution of visceral depots to hepatic FFA delivery is not disproportionately increased (83). *In vivo* studies also show an increased lipolytic responsiveness to isoproterenol and mixed adrenergic agonist (epinephrine), but this does not appear to be due to the enhanced lipolysis in visceral fat depots (84). Thus, the pathophysiologic importance of the alterations in the cellular regulation of lipolysis in visceral fat depots are debatable (16,17).

#### **E Triacylglycerol Synthesis in Visceral Fat**

##### **1 Capacity for Glucose Uptake and Conversion to Triglyceride**

If lipolysis is higher in visceral adipocytes, maintenance of the size of this depot implies that triglyceride synthesis must be increased in parallel. *In vivo* studies (85)

demonstrated that the uptake of orally administered labelled triolein was greater in omental than in subcutaneous adipose tissues of lean to moderately obese men. Consistent with the idea that triglyceride turnover is increased in omental fat cells, glucose transport and glut4 mRNA and protein expression tended to be higher in omental than in subcutaneous (71), though one study found the opposite result with respect to glut4 mRNA (86). *In vitro* studies of glucose metabolism in omental and subcutaneous adipose tissue are few. One study found that in the presence of glucose and fatty acids, omental exhibited lower rates of glucose conversion to total lipids, with lower relative rates of conversion of triacylglycerol, but higher conversion of diacylglycerol (77). The physiological meaning of the apparently lower acylglycerol synthesis in omental adipose tissue is unclear. The fact that glucose transport capacity is at least as high in omental fat cells indicates that under *in vivo* conditions where fatty acid delivery is high, rates of triacylglycerol synthesis *in vivo* must be at high enough to balance the greater rate of lipolysis. *In vivo* factors such as regional differences in blood flow or innervation may also influence rates of triglyceride deposition and lipolysis in omental versus subcutaneous adipose tissues.

##### **2 Acylation-Stimulating Protein**

Acylation-stimulating protein (ASP), or C3a desarg, is a circulating protein that is synthesized in adipose tissue among other tissues (87,88). Serum ASP concentration, as well as adipose production, rises after a meal and stimulates triacylglycerol synthesis in an additive fashion with insulin. The binding capacity and affinity of subcutaneous fat cells exceed those of omental in both lean and obese subjects, and in both males and females (88). ASP is thought to act by stimulating diacylglycerol acyltransferase. It seems reasonable to hypothesize that its lower activity in omental may explain the relatively higher accumulation of newly synthesized diacylglycerol in this depot (77). No previous studies have examined regional differences in ASP production, although one small study showed no higher production of adipisin, the precursor of ASP, in omental adipose tissue (89). Although adipose tissue is not the sole site of ASP production *in vivo*, further studies of regional differences in its production appear warranted. It seems possible that local production of ASP is higher in omental, leading to a downregulation of its receptor affinity or number; thus, the net effect of ASP in omental and subcutaneous adipocytes may depend on the balance of its concentration and activity. The

finding that subcutaneous adipocytes of obese women show the highest affinity for ASP suggests that this protein may promote subcutaneous fat deposition.

### 3 Lipoprotein Lipase

The activity of lipoprotein lipase (LPL) is responsible for local hydrolysis of circulating triacylglycerol that provide fatty acids for storage or utilization within peripheral tissues. LPL activity in omental vs subcutaneous adipose tissue is reportedly similar (in men) or slightly lower (women) (69,90). A number of studies did not find differences in LPL activity or its mRNA expression in omental versus subcutaneous adipose tissue, probably because of the small number of subjects and studies and the pooling of men and women, or expression of data on a per-gram rather than a per-fat cell basis (65,67,75,91). *In vivo* analysis shows that LPL provides an excess of triglyceride fatty acids to the adipocytes to be esterified in subcutaneous adipose tissue (92). Thus, it seems likely that there is sufficient LPL activity to provide ample substrate (FA) for high rates of triacylglycerol synthesis in both depots *in vivo*. However, there are no data comparing regional differences in omental versus subcutaneous LPL activity in the fed state (because of problems sampling the omental depot).

Differences in the activities of enzymes and proteins involved in regulating adipocyte triacylglyceride metabolism as a function of changes in nutritional status may derive from altered responsiveness to chronic effects of hormones on their expression. For example, omental adipose tissue is more responsive to glucocorticoid and less responsive to insulin. Whereas culture with dexamethasone increases LPL expression in omental adipose tissue, no effect is observed in subcutaneous adipose tissue. Conversely, culture with insulin leads to increased LPL activity in subcutaneous but not omental adipose tissue (68).

Depot differences in the expression or activity of key transcription factors such as sterol regulatory element binding protein-1c/ADD1 and peroxisome proliferator receptor- $\gamma$  may be of importance determinants of depot differences in the expression of lipogenic genes, including LPL (93,94).

### F Fatty Acid Transport and Metabolism

Omental adipocytes appear to have an increased intrinsic capacity to take up fatty acids. Kirkland's laboratory demonstrated that fatty acid transport was higher in newly differentiated preadipocytes derived

from human omental than in subcutaneous adipose tissue (95). Depot differences in rates of fatty acid uptake and the activities of acyl CoA synthetases, and in expression of fatty acids binding proteins (adipocyte and keratinocyte are both increased), were also documented. The expression of the adipocyte fatty acid-binding protein and the ratio of the adipocyte to the keratinocyte fatty acid-binding protein were higher in omental than in Sc(96). The biochemical or physiological consequences of alterations in the expression of fatty acid-binding proteins are uncertain, as there are discrepant results in the literature on the phenotype of the adipocyte fatty acid binding protein knockout mouse (97–99).

The fatty acid composition of omental fat does not differ markedly from that of subcutaneous, suggesting no major depot differences in fatty acid metabolism, including desaturase reactions (100).

### G Other Metabolic Differences

Some research attention has addressed a number of other metabolic features of omental adipose tissue. For example, this depot also expresses higher levels of uncoupling protein 2 mRNA, with no gender or obesity effect (101). Only subcutaneous, not omental, fat responded with an increase in UCP2 expression in response to a PPAR $\gamma$  agonist (101). The implications for adipocyte metabolism are not clear at this time.

## VI PHYSIOLOGICAL DETERMINANTS OF VISCERAL ADIPOSE TISSUE FUNCTION

The major metabolic differences between omental and subcutaneous adipose tissues are summarized in Table 2. It is tempting to speculate that adipocytes of the visceral versus subcutaneous depots represent different "types" of fat, with intrinsic, genetically programmed differences in functional capacities. Such "intrinsic" differences could explain the differential growth of these two fat compartments as a function of developmental stage, age, endocrine status, genetics, and disease (1). The concomitant growth of visceral fat while subcutaneous fat depots become depleted in patients with acquired immunodeficiency syndrome provides yet another indication that these depots are functionally distinct "types" of fat. However, it is equally plausible that the local environment within these fat depots, i.e., blood flow, innervation, and paracrine influences, leads secondarily to the variations in metabolism.

**Table 2** Summary of Differences Between Omental (Om) and Abdominal Subcutaneous (SC) Adipose Tissues

---

|   |
|---|
| A. Metabolism   |
| 1. Lipolysis  |
| a. Basal (Om < SC)  |
| b. Response to stimulatory agonist                            |
| 1. Beta-adrenergic (Om > SC)                                  |
| c. Response to inhibitory hormones                            |
| 1. alpha2-adrenergic (Om < SC)                                |
| 2. insulin (omental < SC)                                     |
| 3. adenosine (omental < SC)                                   |
| 2. Triglyceride deposition                                    |
| a. lipoprotein lipase activity (Om < SC in females)           |
| b. glucose transport (basal and insulin-stimulated, Om < SC)  |
| c. glucose conversion to triacylglycerol (Om < SC)            |
| d. glucose conversion to diacylglycerol (Om > SC)             |
| e. acylation stimulating protein (Om < SC)                    |

| 1. PAI1 (inconsistent reports)                                |
| D. Expression of transcription factors                        |
| 1. SREBP1c (SC > Om)  |
| 2. PPAR $\gamma$ (SC = Om)                                    |

---

## A Blood Flow

Blood flow to the rat mesenteric fat pad is about five-fold higher than other intra-abdominal depots (102,103). Other than casual observations that visceral adipose tissues are highly enriched in endothelial cells, suggesting high vascularization, no published information is available comparing the rate of blood flow or its regulation in these depots in humans.

## B Innervation

We could find no data comparing the sympathetic innervation of human visceral versus subcutaneous adipose tissues. In the rat, mesenteric adipose may receive a richer sympathetic input than subcutaneous or other intra-abdominal depots (104,105).

## C Hormonal Determinants

### 1 Sex Steroids

Studies in transsexuals given hormone replacement indicate that estrogen produces proportionately greater

increases in subcutaneous than in visceral fat (106). Testosterone administration to female-to-male transsexuals decreased subcutaneous fat but increased visceral fat (106,107). In contrast, Marin et al. (85) found that testosterone decreased the deposition of radio-labeled triglyceride into omental and retroperitoneal fat. This result is consistent with the finding that serum testosterone is negatively correlated with visceral fat area in men (108,109). It appears that the effects of sex steroids on visceral fat deposition vary in men and women, perhaps owing to the effects of progestins (106).

The biochemical or molecular basis for the regional differences in sex steroid effects on adipose metabolism are not well elucidated. However, estrogen appears to produce a greater stimulation of preadipocyte proliferation in subcutaneous than in omental fat (110,111). Also, estrogen and testosterone influence the expression of adrenergic receptors through direct effects on the adipocyte (112–116).

### 2 Growth Hormone

Administration of growth hormone tends to selectively deplete visceral fat mass as analyzed by CT (117–121). Chronic growth hormone decreases lipoprotein lipase activity and increases basal lipolysis (122) *in vitro*. To our knowledge, there are no *in vitro* studies comparing the sensitivity or responsiveness to the effects of growth hormone on adipocyte metabolism in visceral versus subcutaneous adipose tissue of humans.

### 3 Cortisol

Cortisol excess (Cushing's syndrome) is associated with a truncal and visceral accumulation of fat, often with wasting of peripheral fat that is reversible with therapy (123). The metabolic basis of this is altered fat distribution thought to be the increased number of glucocorticoid receptors on omental versus subcutaneous fat cells (1,31,124–127). Additionally, greater responsiveness, but not sensitivity, to glucocorticoid effects has been demonstrated in omental versus abdominal subcutaneous adipose tissues of obese humans (68,128).

Cortisol can be synthesized locally within adipose tissue. HSD1 activity is higher in stromal cultures derived from omental as compared to subcutaneous fat (129,130). It has been suggested that higher local production of cortisol in omental may produce visceral obesity by promoting local hypertrophy of adipocytes, essentially "Cushing's" of the omentum (129). Further studies of regional HSD1 activity in subjects of varying degrees of visceral adiposity are needed to test this

attractive hypothesis. No information is available on variations in visceral and subcutaneous HSD1 activity as a function of gender, age, fat distribution, or metabolic status.

Proof of principle that local cortisol production within adipose tissue can lead to visceral obesity was recently reported. Transgenic mice in which the aP2 promoter was used to drive expression of the gene for HSD1 in adipose tissue exhibited the preferential growth of mesenteric fat, as well as a generalized increase in fatness (20), particularly when placed on a high-fat diet. It seems likely that the increased growth of the mesenteric fat depot was due to increased glucocorticoid receptor expression (127), as supported by the observation that the expression of lipoprotein lipase was markedly increased in this depot. This new mouse model strongly supports that hypothesis that local production of cortisol within adipose tissue can drive fat deposition and that depot variations in the local production of cortisol (or responsiveness to its action) are important determinants of regional adiposity.

#### **D Genetic Determinants of Visceral Adiposity**

It appears that genes factor in the control of the size of visceral fat stores, independent of total fat mass in humans (23,131) and in a mouse model (41). A number of candidate genes and loci that modulate visceral fat deposition were identified, including several that are involved in steroid metabolism and food intake regulation (23,132). One interesting possibility is that polymorphisms in the glucocorticoid receptor gene may also exert an effect on regional fat distribution (133,134). Heterozygosity for a missense mutation in the melanocortin-4 receptor gene was associated with higher visceral adiposity and morning cortisol levels (132).

#### **E Effect of Thiazolidinedione (TDZ) Drugs on Fat Distribution**

The antidiabetic TDZs are ligands of peroxisome proliferating-activating receptor- $\gamma$  (PPAR $\gamma$ ) and thus increase adipogenesis as well as improving insulin sensitivity. TDZs appear to be less potent in stimulating preadipocyte differentiation in cultures derived from human omental versus subcutaneous fat depots despite similar levels of PPAR $\gamma$ . Clinical studies show that treatment of type 2 diabetics with troglitazone leads to a selective decrease in visceral adiposity and may also increase the mass of subcutaneous fat stores (135,136).

This TDZ is no longer in clinical use, and there are as yet no reports of other TZD effects on human fat distribution. In rats, pioglitazone has more potent adipogenic effects on intraabdominal depots (ovarian and retroperitoneal vs. subcutaneous fat, the mesenteric was not examined) (137).

### **VII ENDOCRINE AND SECRETORY FUNCTIONS OF VISCERAL ADIPOCYTES AND ADIPOSE TISSUE**

#### **A Endocrine Function of Visceral Adipose Tissue**

Adipose tissue is now recognized as an important endocrine organ that produces protein hormones including leptin, interleukin-6 (IL-6), adiponectin (also known as ACRP30 or adipoQ), angiotensinogen (and all components of the renin angiotensin system), and resistin (21,138). Considerable depot differences in leptin production add to the concept of the visceral adipocytes as a functionally distinct subtype of adipocytes. The lower leptin production by omental may not be an intrinsic property, however, because long-term culture with insulin plus dexamethasone abolished this depot difference (128). Thus, in vivo factors such as increased responsiveness of omental adipocytes to  $\beta$ -adrenergic agonists may contribute to the lower leptin expression (139). Depot differences in IL-6 production, however, persist after long-term culture (62). The majority of the tissue IL-6 derives from nonadipose (stromal) cells within adipose tissue. Differences in the cellular composition of visceral versus subcutaneous adipose tissues may therefore have pathophysiological implications, and deserve further study. The fact that the size of different fat depots is regulated by different genes in mice strongly supports the concept of different "types" of fat, although secondary effects cannot be ruled out (41).

##### **1 Leptin Expression Is Lower in Visceral Adipose Tissue**

The adipocyte hormone leptin has been studied extensively with regard to depot differences. Omental adipose tissue expressed lower levels of leptin mRNA, and produces less leptin (per cell or per gram) independent of fat cell size in lean and obese men and women (63,89,128,140,141). Thus, omental adipose tissue production of leptin is a minor determinant of systemic levels, but may be of importance via its impact on hepatic metabolism via the portal circulation.

## B IL-6 Production Is Higher in Omental Than in Subcutaneous Fat

IL-6 is considered an adipose hormone because arteriovenous studies show a net release of IL-6 across the abdominal subcutaneous fat in vivo (16,142,143). Of note, in vivo and in vitro production of IL-6 in subcutaneous fat and serum IL-6 levels are increased in proportion to BMI (144,145). One study indicates that omental produces more IL-6 in severely obese subjects (men and women) (62). Further studies of omental IL-6 production in lean and moderately obese subjects are needed, because it could be playing an important paracrine as well as endocrine role. It has been suggested that IL-6 overproduction by visceral fat delivered directly to the liver via the portal vein may contribute to the development of the metabolic syndrome (62). Animal studies show that IL-6 increases VLDL production and increasing the synthesis of acute phase proteins, both features of visceral obesity. Most of the IL-6 produced derives from stromal elements, but adipocytes also appear to produce it (62). More needs to be known about cell-specific and depot-specific regulation of IL-6 synthesis and secretion. Interestingly, isoproterenol administration in vivo appears to increase serum and adipose tissue IL-6 (145–147). As the omental depot is more responsive to  $\beta$ -adrenergic effects, this may be one factor in the increased omental production of this cytokine.

High levels of omental IL-6 and perhaps other cytokines (if they are secreted from the omentum) may also greatly impact hepatic metabolism. Both these hormones may contribute to hepatic insulin resistance, and IL-6 is a potent stimulator of hepatic VLDL production and the acute phase protein synthesis that appears to be a feature of visceral obesity (148–150).

### 1 Expression of Other Cytokines in Visceral Fat

Adipose tissue also synthesizes a number of cytokines (TNF $\alpha$ , IL-1 $\beta$ , IL-8, IL-10) and chemokines (146,151–156) that appear to act mainly on the paracrine level. Depot differences in cytokine production have not been extensively studied. Tumor necrosis factor- $\alpha$  does not appear to be released from adipose tissue (at least from the subcutaneous depot), and may therefore serve an exclusively paracrine role. Several studies have not found a depot difference in TNF expression (22,89). Other cytokines have not been examined for possible depot differences.

The expression of the cellular inhibitor of apoptosis protein 2 is higher in omental and subcutaneous pre-

adipocytes (89,157). However, this depot difference does not persist after culture of preadipocytes derived from each depot (157), suggesting an altered pro-apoptotic environment in vivo, in omental fat.

### 2 Adiponectin

The adipocyte hormone adiponectin is implicated in the pathogenesis of insulin resistance (158–160). The extent of the reduction of adiponectin expression in subcutaneous fat in type 2 diabetes appears to be less than in omental fat (161), but depot differences in its expression are not yet well characterized.

### 3 Sex Steroid Metabolism

Estrogen is produced via P450 aromatase that is expressed in the stromal compartment of adipose tissue, particularly in postmenopausal women (162). Adipose tissue also possesses enzymes involved in androgen metabolism (109). Possible depot differences in sex steroid metabolism have not yet been extensively studied. However, there appears to be evidence to depot-specific estrogen action. The estrogen receptor- $\alpha$  limits fat deposition (163,164). The expression of the estrogen receptor- $\alpha$  is poorly feedback-regulated in human omental as compared to subcutaneous fat, suggesting a mechanism for depot-specific effects of estrogen on fat distribution (165). Additionally, estrogen receptor- $\beta$  is expressed in lower relative abundance in omental than subcutaneous adipose tissue of women and men (116), but the physiological implications of this observation are unclear.

### 4 Cortisone-Cortisol Interconversion in Visceral Versus Subcutaneous Fat: Endocrine Aspects

As discussed in Section IV.C.3, adipose tissue is also a site of conversion of cortisone (inactive) to cortisol (active). 11-Beta-hydroxysteroid dehydrogenase 1 (HSD1) is expressed in both stromal and fat cells where it may serve an endocrine as well as a paracrine role (166–169). In vivo, arteriovenous difference studies show that there is a net production of cortisol across the abdominal subcutaneous fat depot (170), indicating that adipose tissue may participate in the increased cortisol turnover observed in the obese (170). Although HSD1 activity was found to be lower in cultures of stromal cells from subcutaneous vs omental fat (129), homogenates of subcutaneous adipose tissue were able to convert cortisone to cortisol, and the activity was increased in obese men (171). Because of the greater volume of subcutaneous adipose tissue, this depot may be a more

important contributor to circulating cortisol levels than visceral depots.

## 5 Renin-Angiotensin System

All components of the renin-angiotensin system are expressed in adipose tissue, and expression is increased in obesity and response to nutritional alterations. Omental adipose tissue appears to express higher levels of angiotensinogen, particularly in the obese (22,172,173).

## C Adipocyte Secretory Products Involved in Systemic Metabolism: Contribution from Visceral Versus Subcutaneous Fat

Adipose tissue also secretes proteins involved in lipid and lipoprotein metabolism [cholesterol ester transfer protein (CETP), phospholipid transfer protein (PLTP), ASP, apolipoprotein E], as discussed previously (174). CETP expression is higher in subcutaneous than omental fat, but PLTP does not differ (172); apoE expression has not yet been studied. ASP expression in omental versus subcutaneous fat was discussed in Section V.B.4.

## D Omental Adiposity and Fibrinolysis

Proteins involved in fibrinolysis, including plasminogen activators and plasminogen inhibitor 1 (PAI1), are expressed in adipose tissue (175). Many authors have found that PAI1 expression is higher in omental than in subcutaneous fat (22,176–178), but others find an elevation with obesity but no regional difference (179,180). The source of the PAI1 production in samples of human adipose tissue is unclear (54), and human preadipocytes in culture derived from omental and subcutaneous fat release similar amounts of PAI1 (181). In addition, whether subcutaneous fat actually releases PAI1 to the systemic circulation has been questioned (182). The degree to which the depot-specific production of PAI1 accounts for the association of hypercoagulability with the metabolic syndrome require further *in vivo* and *in vitro* studies, but local actions within each adipose depot are also likely. For example, PAI1 may promote preadipocyte migration and cluster formation during adipogenesis (183). Furthermore, obese (obob) mice null for PAI1 showed lower TNF $\alpha$  expression in fat and improved insulin sensitivity, providing a potential mechanism linking adipose PAI1 expression to metabolic complications of obesity (184).

## E Lipodystrophies

Depletion of subcutaneous fat stores occurs in cases of genetic and acquired lipodystrophies (185). The fat maldistribution associated with the acquired immunodeficiency syndrome (186) provides a dramatic example of differences between visceral and subcutaneous fat depots. The central adiposity in this syndrome may be exacerbated by protease inhibitors, but were reported before the use of these drugs (186). Whether the adipose tissue depots have a special role in responding to the immune challenge remains to be determined (187,188). Depot differences in responsiveness or altered sensitivity to catabolic or apoptotic effects of systemic or local cytokines may contribute to depot differences in responses to altered metabolic states.

# VIII THERAPEUTIC STRATEGIES FOR REDUCTION OF VISCERAL ADIPOSITY

## A Methodological Considerations

As reported above, the correlation coefficients between VAT and metabolic risk factors appears to be relatively constant independent of the level of the abdomen at which VAT is measured. Preliminary evidence also suggests that the mobilization of VAT (cm<sup>2</sup>) in response to weight loss at different levels of the abdomen are comparable (35,189,190); that is, the relative reduction observed at the level of L4-L5 is not different from that observed at the L2-L3 level. The relatively uniform reduction in VAT remains true independent of the method of inducing weight loss (e.g., diet- or exercise-induced weight loss) (189). Although this observation is based in large measure on data from Caucasian men and women, Conway et al. (49) report that in obese African-American women the reductions in VAT at the L2-L3 level are not different from those observed at the L4-L5 level.

Illustrated in Figure 5 is the influence of weight loss on both VAT and abdominal subcutaneous adipose tissue in a large cohort of overweight and obese men and women. Inspection of Figure 5 reveals that the relative (%) reduction in VAT area (cm<sup>2</sup>) for four MRI images obtained in the abdomen is uniform and similar to the relative reduction in VAT mass derived using the four abdominal images. These data suggest that the influence of weight loss on VAT determined using a single CT or MR image obtained in a region bordered by S1-L5 and about L2-L3 will provide similar results. In other words, the distribution of VAT does not appear to be influenced by weight loss in the order of 10% (35,189).

**Figure 5** Relative reduction in visceral and abdominal subcutaneous adipose tissue at the L4-L5 level, 5 cm below, 5 cm above, and 10 cm above L4-L5, as well as visceral and abdominal subcutaneous adipose tissue mass derived using five abdominal images. The reductions in visceral and abdominal subcutaneous fat were observed in response to a 10% weight loss in 61 men (left) and 56 women (right). VAT, visceral adipose tissue; ASAT, abdominal subcutaneous adipose tissue.

## B Lifestyle-Based Strategies

### 1 Exercise

The effects of exercise on abdominal adipose tissue distribution have recently been considered and the reader is referred to these citations for detailed reviews (191–193). For simplicity, we review here those studies that consider the effects of exercise with or without weight loss separately on abdominal adiposity, in particular, VAT.

### 2 Exercise Without Weight Loss

Ross et al. (194) observed a 16% reduction in VAT independent of any change in abdominal subcutaneous or total adipose tissue in obese men who performed daily, aerobic exercise (brisk walking, ~60 min) for 3 months. This finding confirms an earlier report wherein Mourier et al. (195) observed large reductions in both VAT (~48%) and abdominal subcutaneous adipose tissue (~18%) in response to moderate exercise performed three times per week for 8 weeks in men and women with type II diabetes. Thomas et al. (196) also examined the effects of exercise training without weight loss in 17 nonobese, healthy women. In that study, the women performed aerobic-type exercise under supervision 3 days per week for 6 months. Despite no change

in total and subcutaneous adipose tissue, a 25% reduction in VAT was observed. Together these results suggest that regularly performed aerobic exercise without weight loss results in marked reductions in VAT, which are in general greater than the change in total or abdominal subcutaneous adipose tissue.

In contrast to these observations, Poehlman et al. (197) report that 6 months of either endurance or resistance exercise training did not reduce VAT or abdominal subcutaneous adipose tissue in young, premenopausal women, a finding consistent with that of DiPietro et al. (198), who report that in older men and women, 4 months of supervised aerobic exercise had no effect on abdominal subcutaneous or visceral adipose tissue. A rationale to explain the equivocal findings is unknown. However, it is noted that in the Poehlman et al. (197) study, the average VAT values pretreatment for the exercise groups approximated 40 cm<sup>2</sup>, a value substantially below the values thought to be associated with metabolic risk (199,200). Taken together, available evidence does not permit firm conclusions regarding the effects of exercise training in the absence of weight loss on VAT distribution.

### 3 Exercise-Induced Weight Loss

Inspection of Table 3 reveals that few studies have examined the effects of exercise-induced weight loss on VAT distribution. Schwartz et al. (1991) report marked reduction in both abdominal subcutaneous (~20%) and visceral (~25%) adipose tissue in response to aerobic-type exercise in older men despite very modest weight loss (2.5 kg) (201). Consistent with the findings of this study, Wilmore et al. (202) report that 5 months of cycling exercise performed three times per week by 557 men and women varying widely in age, race, and adiposity resulted in significant but relatively small reductions in visceral adipose tissue (~6%) in association with a minor change in body weight and total fat (<1 kg). Bouchard et al. (203) studied seven twin pairs who exercised on a stationary bicycle 6 days a week for 3 months such that 1000 kcal was expended each day. In that study, the authors prescribed an isocaloric diet to ensure that the negative energy balance was induced by exercise alone. The exercise program resulted in a 5-kg reduction in body weight that was associated with a 35% and 27% reduction in visceral and abdominal subcutaneous adipose tissue, respectively. Unfortunately, very little is known regarding whether exercise-induced weight loss influences the visceral to abdominal subcutaneous adipose tissue ratio. In other words, whether exercise alters adipose tissue

WL, weight loss; WWL, without weight loss; BMI, body mass index; VAT, visceral adipose tissue; ASAT, abdominal subcutaneous adipose tissue; NR, not reported; L, liters.

<sup>a</sup> Significantly different from change in control group ( $P < .05$ ).

<sup>b</sup> Significant within group change ( $P < .05$ ).

distribution by inducing a greater reduction in visceral versus subcutaneous fat is unclear (191).

#### 4 Diet (Caloric Restriction)

Caloric restriction has been the principal means of assessing the influence of weight loss on VAT (Table 4). From the studies reviewed it is noted that the magnitude of the diet-induced weight loss ranges from 4.4 to 18.8 kg (Table 4). The corresponding reductions in VAT vary according to the weight loss; the greater the weight loss, the greater the reduction in VAT. When expressed per kilogram of body weight lost [mean absolute VAT loss (cm<sup>2</sup>) ÷ mean weight loss (kg)], the corresponding reduction in VAT varied from 2.5 to 13.8 cm<sup>2</sup>/kg. In relative terms (i.e., controlling for initial differences in VAT accumulation), the relative loss per kg is ~3% (4). Thus, for a 10-kg weight loss, the relative reduction in VAT is ~30%. It is important to note the large interindividual variations observed in VAT reduction

(Table 4) and that the observation is generally restricted to obese Caucasian adults.

The data in Table 4 also suggest that in response to diet-induced weight loss, there is a preferential reduction in VAT. Whether the observation is based on data obtained from a single image or by comparing relative reductions in VAT and subcutaneous adipose tissue volume (liters) derived from multiple images, for a given weight loss, the relative reduction in VAT is greater than those observed for subcutaneous adipose tissue (Table 4).

#### 5 Pharmacotherapy

The potential of pharmacotherapy for the treatment of obesity is promising. When used as an adjunct to the traditional approaches of diet- and/or exercise-induced weight loss it would appear that the addition of available pharmacological agents are useful in helping patients achieve and maintain weight loss (204). At

present there is limited evidence regarding the independent influence of the two drugs currently approved for obesity treatment in North America. We are unaware of trials wherein the effects of orlistat, a pancreatic lipase inhibitor, on VAT are considered. Preliminary evidence suggests that the serotonin reuptake inhibitor sibutramine is associated with marked reduction of VAT ( $\sim 22\%$ ) in response to a 6-month trial (205). However, in that trial the subjects received sibutramine in conjunction with a hypocaloric diet and were encouraged to exercise. Given the demonstrated importance of visceral obesity in the development of metabolic risk, further study to consider the independent effects of pharmacotherapy on VAT is warranted.

## IX IS THE METABOLIC SYNDROME DUE TO TOO MUCH VISCERAL OR TOO LITTLE SUBCUTANEOUS FAT?

Although there is agreement in the literature that increased central obesity is associated with a metabolic syndrome that increase risk for development of type 2 diabetes and cardiovascular disease, there is considerable controversy about which fat compartment that is the main culprit. Numerous careful studies find that visceral fat volume is the strongest independent predictor of metabolic risk (insulin resistance, dyslipidemia) in men or women carefully matched for total body fat but differing in visceral fat mass (1,8,206,207). Nevertheless, not all studies assessed whether the associations were independent of total body fat (32,208).

It has been suggested that visceral adiposity was a marker of the metabolic syndrome (i.e., a secondary effect of an altered hormonal milieu that affects fat distribution *and* metabolism), rather than its primary cause (208). Indeed, Abate et al. (32) found that insulin sensitivity was best correlated with the mass of truncal subcutaneous (not visceral or retroperitoneal) fat in nondiabetic middle-aged men and in subjects with NIDDM. More recently, two groups have noted that the relative amount of deep subcutaneous adipose tissue also predicts metabolic risks associated with obesity (36,209). Addition of visceral adipose tissue volume to the equation only slightly increased the regression coefficient. In another study, the size of posterior (vs. anterior) subcutaneous fat stores was best correlated with intra-abdominal (visceral) fat, and was a better predictor of insulin resistance in nondiabetic men (210).

Very little is known about the metabolic features of the deep versus the superficial subcutaneous fat layers,

or posterior versus anterior subcutaneous fat. However, a recent microdialysis study indicates that the superficial subcutaneous fat layer that is usually sampled in adipocyte metabolic studies is more responsive to the lipolytic action of epinephrine compared to deep subcutaneous or preperitoneal depots (211). Thus, deep subcutaneous may be less active than visceral adipose tissue; why its mass correlates with metabolic risk remains obscure. Nevertheless, future studies of the influence of visceral adiposity on systemic metabolic should consider potentially confounding effects of variation in deep subcutaneous fat mass.

It is also possible that the level of visceral adiposity influences the metabolic activity of subcutaneous fat cells, and that this in turn contributes to metabolic abnormalities including increased systemic fatty acid turnover. For instance, decreased sensitivity to the antilipolytic action of insulin was noted in abdominal subcutaneous adipose cells from viscerally obese women (212). In men, subcutaneous adipocytes from viscerally obese patients show higher maximal responses to  $\alpha_2$ -adrenergic receptor agonists, and this may be related to the greater hyperinsulinemia associated with visceral fatness (213). Thus, the influence of visceral fat stores on fatty acid metabolism is likely to be exerted through multiple mechanisms, and may extend beyond the lipolytic activity of the visceral fat cells per se.

Lipectomy of the two main intra-abdominal (but nonportal) adipose tissues of rats, the perirenal and epididymal, led to a marked improvement in hepatic insulin resistance (44). However, this experiment cannot distinguish an effect of a decrease in total body fat from a regionally specific effect. For instance, it is not known whether removal of subcutaneous fat that produced an equivalent decrease in total body fat would similarly lead to alterations in hepatic insulin action in the rat. Nevertheless, the results of this experiments indicates that nonportal abdominal adipose tissue can influence glucose-insulin homeostasis.

An alternate hypothesis to explain the association between visceral adiposity and metabolic risk is that the metabolic effects of obesity are related to "subcutaneous fat deficiency" (214,215). Indeed, subcutaneous fat lipectomy in hamsters also leads to a metabolic syndrome, despite no measurable increase in the size of the major intra-abdominal depots (214). Thus, subcutaneous fat may be a "safe" place to deposit excess triglyceride, while other tissues, e.g., liver and muscle, as well as visceral fat, may not be (214,216).

Resolution of the controversy on the importance of abdominal subcutaneous versus visceral fat will require studies in which the sizes of specific intra-

abdominal and subcutaneous regions are quantified, e.g., by whole-body MRI or other methods.

## X SUMMARY AND CONCLUSIONS

The relative importance of visceral and subcutaneous abdominal cells in the etiology of the metabolic syndrome is a matter of debate. Nevertheless, the biology of visceral fat remains of considerable interest, as these fat depots undoubtedly play an important, although probably not an exclusive, role in the metabolic derangements associated with abdominal obesity. Abundant evidence indicates that visceral adipose tissue, particularly the better-studied omental depot, has distinct metabolic properties from subcutaneous fat. Recent studies indicate that the influence of the visceral fat depots likely extends beyond glucose and fatty acid metabolism, and includes the regulation of blood pressure, coagulation, and perhaps immunity. Thus, further understanding of the nature of visceral fat depots has far-reaching implications.

It will be essential for our field to better define our use of the term visceral fat. From a clinical and practical perspective, the term indicates all intra-abdominal depots, but from a mechanistic perspective, it is important to distinguish those that are associated with digestive organs and drain portally (i.e., omental and mesenteric). It will also be important to discern whether the metabolic behavior of these "portal" depots is due to intrinsic (genetic) differences among truly different "types" of fat cells, or they are induced by variations in the local neural, endocrine, and paracrine environment within each fat depot.

## ACKNOWLEDGMENTS

We thank Dr. John Kral for insightful discussions and his contributions to Table 1, and Dr. Colleen Russell for helpful comments on the manuscript.

## Resting Energy Expenditure, Thermic Effect of Food, and Total Energy Expenditure

Yves Schutz and Eric Jéquier

University of Lausanne, Lausanne, Switzerland

### I METHODS OF MEASURING ENERGY EXPENDITURE IN HUMANS

#### A Introduction

Three main methods are used to measure energy expenditure in man: indirect calorimetry, direct calorimetry, and the doubly labeled water technique. These methods are based on different principles and do not measure the same type of energy.

*Indirect calorimetry* is the best method to measure resting energy expenditure, the thermic effect of food and the energy expended for physical activity. It has the great advantage of being relatively simple; it can be used either with a ventilated hood system (for a resting subject), or with a respiration chamber, when a 24-hr measurement is needed. A first advantage of indirect calorimetry is the immediate response of oxygen consumption (measured by the method of respiratory gas exchange) in relation with the real oxygen consumption in the tissues and organs within the body. There is no delay in measuring oxygen consumption because the body has negligible O<sub>2</sub> stores. A second advantage of indirect calorimetry in comparison with other methods is the possibility to assess nutrient oxidation rates, when oxygen consumption, CO<sub>2</sub> production, and urinary nitrogen excretion are measured.

*Direct calorimetry* is the method of choice for studies aiming at assessing thermoregulatory responses. The

method consists in measuring heat losses, not heat production. In many circumstances, heat losses differ from heat production and there is a change in heat stored. For instance, after a meal, heat production begins to rise 20–30 min after the onset of eating, whereas heat loss increases only later on; the consequence of the different time courses of heat production and heat loss is a rise in body temperature.

The method of direct calorimetry consists in the measurement of the heat dissipated by the body by radiation, convection, conduction, and evaporation (1). Under conditions of thermal equilibrium in a subject at rest and in postabsorptive conditions, heat production, measured by indirect calorimetry, is identical to heat dissipation, measured by direct calorimetry (Fig. 1). This is an obvious confirmation of the first law of thermodynamics—that the energy released by oxidative processes is ultimately transformed into heat (and external work during exercise). In steady-state conditions, the identity between heat production and heat loss in a resting subject (Fig. 1) corroborates the validity (for the whole body) of the method of indirect calorimetry.

*Doubly labeled water technique* is the third method and is based on the difference in the rates of turnover of <sup>2</sup>H<sub>2</sub>O and H<sub>2</sub><sup>18</sup>O in body water. The subject is given a single oral dose of <sup>2</sup>H<sub>2</sub><sup>18</sup>O to label body water with both isotopes <sup>2</sup>H and <sup>18</sup>O. A rapid exchange of <sup>18</sup>O occurs between water and carbon dioxide owing to the action of carbonic anhydrase. As a result, after

**Figure 1** Metabolic rate ( $\dot{M}$ ), total heat losses ( $\dot{H}$ ), radiative and convective heat losses ( $\dot{R} + \dot{C}$ ), and evaporative heat losses ( $\dot{E}$ ) in a male subject aged 25 years, exposed at 28°C in a direct calorimeter. Note that after 30 min of temperature equilibration within the calorimeter, the values of  $\dot{M}$  and  $\dot{H}$  are similar, indicating that heat production is identical to heat losses.

equilibrium of  $^2\text{H}_2$   $^{18}\text{O}$  in the water pool and equilibrium of  $^{18}\text{O}$  with carbon dioxide,  $^{18}\text{O}$  is lost both as  $\text{H}_2^{18}\text{O}$  and  $\text{CO}^{18}\text{O}$ , whereas  $^2\text{H}$  is lost only as  $^2\text{H}_2\text{O}$ . The difference in the rate of turnover of  $\text{H}_2^{18}\text{O}$  and  $^2\text{H}_2\text{O}$  is an estimate of  $\text{CO}_2$  production rate. In order to calculate the subject's energy expenditure, the mean respiratory quotient (RQ) must be known. Energy expenditure is obtained by multiplying  $\dot{V}\text{CO}_2$  by the energy equivalent of  $\text{CO}_2$  production. The latter varies from 21.0 to 27.7 kJ/L  $\text{CO}_2$  at respiratory quotients of 1.0–0.7, respectively. The disappearance rates of the isotopes can be measured in urine, blood or saliva, for a period equivalent to two to three biologic half-lives. This corresponds to ~14 days in adult subjects. Thus, the method provides a mean value of energy expenditure for a 2-week period. It is not possible to calculate the day-to-day variation in energy expenditure with the doubly labeled water technique.

Several validation studies in both infants and adults have consistently shown a good agreement between the  $\dot{V}\text{CO}_2$  determined by the doubly labeled water and that assessed by indirect calorimetry. Issues have been raised in regard to the question of two-point versus multiple points isotopic sampling, the extent of the fractionation of the isotopes, the difference between the oxygen and hydrogen dilution space, as well as the inherent precision of the analysis by mass spectrometry (2).

Roberts et al. (3) have recently conducted an interlaboratory comparison of the doubly labeled water method using standards containing varying amounts of  $^2\text{H}_2$  and  $^{18}\text{O}$  as well as dose specimens. Surprisingly, there was substantial variability between laboratories in the results, and some laboratories obtained physiologically impossible energy expenditure (i.e., below the resting value). The type of calculation used had little effect on the accuracy of the technique. As a result, the average coefficient of variation for the doubly labeled water method, which is often claimed to be 5%, was not attained by a few laboratories, mostly owing to the quality of the isotopic analysis. The impact of deuterium and  $^{18}\text{O}$  pool size determination on the calculation of total energy expenditure constitutes an important issue (4) since hydrogen tracer dilutes into a pool significantly larger than the body water pool due to the presence of labile hydrogen. This justifies the need for a correction factor for the isotope pool size. It seems that the best approach is to use a pool size based upon the average of the deuterium and  $^{18}\text{O}$  pool space (4).

A recent study by Speakman (5) indicated that the error for  $\dot{V}\text{CO}_2$  estimated by doubly labeled water was not normally distributed. Depending on the difference in the elimination rate constants of the two labels, the duration of the experiment, and the initial isotopic dose, the precision error (99% confidence interval for mean) using duplicate analysis varied enormously (between 3% and 47%). By increasing the number of replicates from two to five, the error could be substantially reduced. The issue of shifts in baseline abundance of deuterium or  $^{18}\text{O}$  tracers is important since it may generate errors in the derivation of  $\text{CO}_2$  and  $\text{H}_2\text{O}$  turnover rates and hence calculated energy expenditure. Jones (6) suggested that optimally the subject should first equilibrate with the new water source when a doubly labeled water study is performed. Alternatively, correction for shifting baseline can be made by measuring isotopic abundance changes in a control group of subjects who do not receive the doubly labeled water dose, but ingest the same diet as the experimental group and perform similar activities.

## **B Indirect Calorimetry: The Method of Choice to Measure Energy Expenditure and Nutrient Oxidation Rates**

### **1 Measurement of Energy Expenditure**

The term "indirect calorimetry" stems from the fact that the heat released by chemical processes within the body can be indirectly calculated from the rate of

oxygen consumption ( $\dot{V}O_2$ ). The main reason for the close relation between energy metabolism and  $\dot{V}O_2$  is that the oxidative phosphorylation in the respiratory chain is coupled with a continuous synthesis of adenosine triphosphate (ATP). The energy expended within the body to maintain electrochemical gradients, to support biosynthetic processes, and to generate muscular contractions cannot be directly provided by nutrient oxidation. Almost all chemical processes requiring energy depend on ATP hydrolysis. It is the rate of ATP utilization that determines the overall rate of substrate oxidation and therefore  $\dot{V}O_2$ . With the exception of anaerobic glycolysis, ATP synthesis is coupled with substrate oxidation. Because there is a proportionality between  $\dot{V}O_2$  and ATP synthesis, and because each mole of ATP synthesized is accompanied by the production of a given amount of heat, one understands the rationale of using  $\dot{V}O_2$  measurement to calculate heat production within the body (7).

The study of the regulation of energy metabolism and nutrient utilization in humans has recently raised a great interest thanks to advances in the construction of open-circuit ventilated hood indirect calorimeters and comfortable respiration chambers.

With the measurement of  $\dot{V}O_2$  (in liters of  $O_2$ /min) at STPD conditions [standard temperature ( $0^\circ C$ ), pressure (760 mmHg), and gas dry], metabolic rate ( $M$ ), which corresponds to heat production, can be calculated (in kJ/min) as follows:

$$M = 20.3 \times \dot{V}O_2 \quad (1)$$

The number 20.3 is a mean value (in kJ/L) of the energy equivalent for the consumption of 1 L (STPD)

oxygen. The value of the energy equivalent of oxygen depends on the composition of the fuel mixture oxidized (Table 1). The error in using Eq. (1) instead of an equation that takes into account the type of fuels oxidized [Eqs. (2) and (3); see below] is not greater than  $\pm 2\%$ .

The heat released by the oxidation of each of the three macronutrients (carbohydrates, fats, and proteins) can be calculated from three measurements: oxygen consumption ( $\dot{V}O_2$ ), carbon dioxide production ( $\dot{V}CO_2$ ), and urinary nitrogen excretion (N).

Simple equations for computing metabolic rate (or energy expenditure) from these three determinations are written under the form:

$$M = a \dot{V}O_2 + b \dot{V}CO_2 - c N \quad (2)$$

The factors  $a$ ,  $b$ , and  $c$  depend on the respective constants for the amount of  $O_2$  used and the amount of  $CO_2$  produced during oxidation of the three classes of nutrients (Table 1). An example of such a formula (Brouwer's equation) is given below:

$$M = 16.18 \dot{V}O_2 + 5.02 \dot{V}CO_2 - 5.99 N \quad (3)$$

where  $M$  is in kilojoules per unit of time,  $\dot{V}O_2$  and  $\dot{V}CO_2$  are in liters STPD per unit of time, and  $N$  is in grams per unit of time. Slightly different factors for the amounts of  $O_2$  used and of  $CO_2$  produced during oxidation of the nutrients are used by other authors, and the values for the factors  $a$ ,  $b$ , and  $c$  are modified accordingly. The difference in energy expenditure calculated by the various formulae is not greater than 3%. Detailed information about these calculations is given elsewhere (9,10).

**Table 1** Oxygen Consumed,  $CO_2$  Produced, and Heat Released from Oxidation of Nutrients

| Nutrients   | $O_2$<br>consumed <sup>a</sup> | $CO_2$<br>produced <sup>a</sup> | RQ   | Heat released<br>(per gram) |        | Energy equivalent (per liter STPD) of: |        |               |        |

Source: Ref. 8.

## 2 Measurement of Nutrient Oxidation Rates

As an example, let us assume that a subject is oxidizing  $g$  grams per minute of carbohydrate (as glucose),  $f$  g/min of fat, and is excreting  $n$  g/min of urinary nitrogen. The following equations, based on Table 1, describe  $\dot{V}O_2$  and  $\dot{V}CO_2$ :

$$\dot{V}O_2 = 0.746 g + 2.02 f + 6.31 n \quad (4)$$

$$\dot{V}CO_2 = 0.746 g + 1.43 f + \sim 5.27 n \quad (5)$$

We can solve Eqs. (4) and (5) for the unknown  $g$  and  $f$  as follows:

$$g = 4.59 \dot{V}CO_2 - 3.25 \dot{V}O_2 - 3.68 n \quad (6)$$

$$f = 1.69 \dot{V}O_2 - 1.69 \dot{V}CO_2 - 1.72 n \quad (7)$$

Because 1 g urinary nitrogen arises from  $\sim 6.25$  g protein, the protein oxidation rate ( $p$  in g/min) is given by the equation:

$$p = 6.25n \quad (8)$$

Other metabolic processes (such as lipogenesis, gluconeogenesis, and ketogenesis) may influence the calculated oxidation rates of nutrients. However, intermediate metabolic processes do not influence the results of Eqs. (6) and (7), provided intermediate substrates do not accumulate within the body or are not excreted from the body. When there is accumulation or excretion of an intermediate or end product other than  $CO_2$  and  $H_2O$ , this approach to compute the oxidation rates of nutrients is no longer valid, and correction factors must be applied to take into account the changes in the pool size of the intermediates or end products.

## II RESTING AND BASAL METABOLIC RATES (RMR AND BMR)

### A Whole-Body, Organ, and Tissue Metabolic Rates

There is an arbitrary distinction between RMR and BMR in the literature. RMR may be considered equivalent to BMR if the measurements are made in post-absorptive conditions. It seems difficult to partition RMR into various subcomponents since the metabolic rates of individual organs and tissues are difficult to assess in humans under noninvasive experimental conditions. By measuring the arteriovenous difference in concentration of  $O_2$  across an organ or tissue, combined with the assessment of blood flow perfusing this organ or tissue, the  $\dot{V}O_2$  of an organ or tissue can be estimated in vivo (based on the reverse Fick equation), but this requires invasive procedures such as arterial and venous catheterization. The error of measurement will largely increase if the rate of blood perfusion of an organ is high compared to its  $\dot{V}O_2$ , indicating a low arteriovenous oxygen difference.

Elia (11) has written an excellent review of the contribution of organs and tissue to the metabolic rate. The major part of the whole-body RMR stems from organs with high metabolic activity such as the liver, kidneys, brain, and heart, although these account for a small proportion of the total body weight (5%; Table 2). Per unit body weight, the kidneys and heart have a metabolic rate more than twice as high as the liver and the brain. In contrast, the metabolic rate of muscle per unit body weight is nearly 35 times lower than that of the heart and kidneys. Since the propor-

**Table 2** Contribution of Different Organs and Tissues to Total Body Weight and Basal Metabolic Rate (BMR) in an Average Man of 70 kg with a BMR of 1680 kcal/day (7.03 MJ/day)

|   | Tissue or organ weight (kg) | Contribution of tissue or organ weight to body weight (%) | Organ metabolic rate per unit weight (kcal/kg/day) | Contribution to BMR (% total) |
|---|-----------------------------|---|--|-------------------------------|
| Liver   | 1.8                         | 2.6   | 200  | 21                            |
| Brain   | 1.4                         | 2.0   | 240  | 20                            |
| Heart   | 0.33                        | 0.5   | 440  | 9                             |
| Kidneys   | 0.31                        | 0.4   | 440  | 8                             |
| Muscle  | 28.0                        | 40.0  | 13   | 22                            |
| Adipose tissue  | 15.0                        | 21.4  | 4.5  | 4                             |
| $\Delta$ = miscellaneous tissues (bones, skin, intestines, lungs, etc.) | 23.2                        | 33.1  | 12   | 16                            |
| Total   | 70.00                       | 100   | 24   | 100                           |

Source: Ref. 11.

tion of muscle to nonmuscle changes with age from birth to adulthood, the RMR per unit body weight is not constant with age (12). The tissue with the lowest metabolic activity per unit body weight is adipose tissue, which accounts for only 4% of the whole-body RMR in nonobese subjects. Calculations show that this value can increase up to 10% or more in obese subjects with a large excess in body fat (Schutz et al., unpublished). The “residual” metabolic rate (16%) not explained by the tissues and organs mentioned above can be accounted for by skin and intestines (which have a relatively large protein mass and protein turnover), as well as bones and lungs.

### **B Body Composition: Effect of Fat-Free Mass and Fat Mass**

The excess body weight of the obese is primarily constituted by fat tissue, but also a small component of associated lean tissue. Although the exact nature of extra lean tissue in obesity is largely unknown, it seems logical to expect a greater absolute RMR in obese adults (13) and children (14) characterized by an excess fat mass and a slight increase in fat-free mass (FFM). Numerous studies have demonstrated that the major factor explaining the variation in RMR between individuals is FFM (15). FFM is a heterogeneous component that can be partitioned into muscle mass and nonmuscle mass. Unfortunately, there is no simple and accurate way to assess these two subcomponents. Owing to the larger variation, between individuals, in fat mass, as compared to FFM, and because, in grossly obese women, fat mass can represent a nonnegligible component of total RMR, the prediction models for RMR that include both FFM and fat mass explain significantly more variance in RMR than FFM alone (15). In addition, age, sex, and family membership are additional factors which should be taken into account.

The effects of gender on resting metabolic rate are explained by differences in body composition. Caution should be used when comparing resting metabolic rate expressed per kilogram FFM in men and women, because the composition of FFM is influenced by gender. The muscle mass of men being larger than that of women, this fact tends to lower the value of RMR per kilogram FFM in men when compared to that of women. This is explained by a greater component of a tissue with a low metabolic rate (resting muscle) in men than in women (Table 2). According to recent data (16,17), women have a lower RMR than men (3–10%) even after adjustment for FFM, fat mass, age, and  $\text{VO}_2\text{max}$ . Various mechanisms could explain this obser-

vation such as hormonal status, differences in the composition of the FFM, muscular fiber type composition (18), and Na,K-ATPase activity (19) as well as differences in the activity of the neoglucogenic pathway, differences in the central body temperature and sympathetic nervous system activity (16).

Physiological variations in sex hormones during the phases of the menstrual cycle in women offer the opportunity to assess, in addition to the change in basal body temperature, the effect of hormonal variation on RMR. Previous studies have indicated an increase in RMR (20) and sleeping metabolic rate (21) in the luteal phase of the menstrual cycle, although recent data in Indian (22) and Dutch (23) women did not show any differences. In a study in which heat production and heat losses were measured by both direct and indirect calorimetry (24), we failed to find any significant differences in RMR (heat production) and heat losses during the luteal phase of the menstrual cycle in young women. By combining indirect calorimetry, direct calorimetry, and thermometry, skin thermal conductance and skin blood flow could be calculated. We observed a decrease in these two latter parameters during the luteal phase that indicates an increase in cutaneous thermal insulation. We concluded that during the luteal phase, the decreased thermal conductance in women exposed to a neutral environment allows the maintenance of a higher internal temperature (24).

Aging leads to a progressive decrease in RMR. Classically, this has been attributed to the reduction in muscle mass accompanying aging (25). A drop in the metabolic activity per unit tissue mass is also likely to occur if the loss of FFM does not fully account for the lower RMR (26). In a recent study, we explored the change in RMR and whole body protein turnover in healthy elderly and lean Gambian men (27). It was found that adjusted for FFM, the RMR was significantly lower (by 13%) in elderly than in young individuals. This was not explained by a decrease in protein turnover, since the protein turnover adjusted for FFM was not different between the two groups. The extent of the decline in RMR in obese male and female individuals remains to be investigated.

### **C Effect of Previous Dietary Intake**

Postabsorptive RMR (or BMR) is typically measured 12 hr after the last meal, in order to diminish the effect of “residual” postprandial thermogenesis. Nevertheless, the relative composition of the diet eaten the previous days (i.e., the food quotient; FQ), largely influences the respiratory quotient during postabsorptive RMR (28).

Isocaloric substitution of low versus high carbohydrate diets have much more influence on the RQ than on the rate of RMR (29). The extent to which short-term overfeeding will increase both the RQ and the RMR depends on the duration of overfeeding: one single-day surfeit energy intake increases the RQ above the FQ (indicating fat storage), but the rise in RMR is very limited and most of the effect is seen on dietary-induced thermogenesis (30).

#### D Hormonal Factors

Many studies have demonstrated that catecholamines increase RMR (31–33). Both  $\beta_1$  and  $\beta_2$ -adrenoceptors are involved in this sympathetically mediated thermogenesis (34). Subcutaneous or intravenous injections of epinephrine increase the RMR by about 20% with large interstudy variation and in a dose-dependent manner (31). Many different organs are involved in the epinephrine-mediated thermogenesis, but the major part of the effect seems to occur in skeletal muscles and in the heart. The mechanism by which epinephrine exerts its thermogenic action may be via a specific stimulation at the cellular level, extrasubstrate cycling (e.g., Cori cycle), and activation of skeletal muscle and cardiac activities.

It is well known that thyroid hormones increase BMR since BMR measurement was used, several decades ago, as a diagnostic tool of hyperthyroidism until hormonal concentrations could be determined. Hyperthyroid patients have an increased metabolic rate which is dependent upon the T3 plasma concentration and may reach up to 180% of the standard reference value (34). There is no general agreement about the mechanisms whereby thyroid hormones stimulate heat production; they may increase the Na,K-ATPase activity in various tissues and may stimulate the rate of protein turnover. Thyroid hormones also potentiate the effects of the sympathetic nervous system at the level of the adrenergic receptor and adenyl cyclase complex. Thyroid hormones act in a permissive manner to allow sympathetic activity to accelerate production of heat.

#### E Familial and Genetic Effects

Almost two decades ago, Bogardus et al. (35) observed that part of the unexplained variance in RMR could be accounted for by family membership, indicating that the level of RMR is partially genetically determined. The twins studies of Bouchard et al. (36) have shown that the RMRs of monozygotic twins have more resem-

blance than that of dizygotic twins after statistical adjustment for differences in body size and body composition. An excellent account of the part played by genetic factors in the etiology of human obesity as well as their metabolic implications has been published by Bouchard (37).

#### F Uncoupling Proteins and Energy Expenditure

Mitochondria of brown adipose tissue have an inducible proton conductance catalyzed by an uncoupling protein, UCP<sub>1</sub> (38). Cold exposure in rodents induces UCP<sub>1</sub> mRNA and protein in brown adipose tissue. The activated UCP<sub>1</sub> catalyzes proton leak across the mitochondrial inner membrane leading to an increased heat production which is called nonshivering thermogenesis (NST). It was then shown (39) that NST was used by rodents not only to protect against cold stress, but also to maintain energy homeostasis in response to excessive caloric intake through an efficient control of adaptive thermogenesis. In rodents, obesity can arise from impaired adaptive thermogenesis, and pharmacological stimulation of brown adipose tissue thermogenesis by  $\beta_3$ -adrenoreceptor agonists is an effective mechanism for reducing obesity (40). In adult humans, however, the absence of detectable brown adipose tissue depots explains why adaptive thermogenesis in response to overfeeding is lacking (41); it also accounts for the failure of  $\beta_3$ -adrenoreceptor agonists as potential therapeutic agents to treat human obesity (40).

The recent discovery of homologs of UCP<sub>1</sub>, particularly the expression of high levels of UCP<sub>2</sub> mRNA in white adipose tissue and of UCP<sub>3</sub> mRNA in skeletal muscle of humans, has given hope that mechanisms unrelated to UCP<sub>1</sub> and to brown adipose tissue might be involved in the stimulation of energy expenditure (42,43). Several studies indicate that these UCPs also have proton transport activity across the mitochondrial inner membrane (42,43). Since UCP<sub>2</sub> and UCP<sub>3</sub> have uncoupling activity and are expressed widely, it has been proposed that they could contribute to adaptive thermogenesis. However, the observation that the expression of UCP<sub>2</sub> and UCP<sub>3</sub> messenger RNA increases with starvation, a condition known to be associated with a reduction in energy expenditure, argues against the view of a role of UCP<sub>2</sub> and UCP<sub>3</sub> in stimulating adaptive thermogenesis.

The conditions that modulate expression of UCP<sub>2</sub> and UCP<sub>3</sub> messenger RNA have been much studied over the past 2 years. Expression of UCP<sub>2</sub> mRNA was found to be elevated in white adipose tissue of obese animals, but discordant results were reported on UCP<sub>2</sub>

expression in white adipose tissue of obese humans (44). Regarding stimulation of UCP<sub>3</sub> mRNA expression, increased circulating free fatty acids levels play a major role (45). Thus, starvation, which is characterized by elevated circulating free fatty acids, is accompanied by a stimulation of UCP<sub>3</sub> (and also UCP<sub>2</sub>) expression in skeletal muscle. These UCPs have therefore no thermogenic effect (because energy expenditure is reduced by starvation), but they may play a role in the stimulation of lipid oxidation (46).

In conclusion, while it is well documented that UCP<sub>1</sub> increases energy dissipation in brown adipose tissue and thus plays a major role in thermoregulation of rodents and human newborns, it is not yet established whether or not UCP<sub>2</sub> and/or UCP<sub>3</sub> are involved in the regulation of energy metabolism. Recently, J.E. Silva (47) postulated that the activity, rather than the concentrations of these uncoupling proteins, could be regulated; the capacity of the cells to produce their energetic currency, ATP, is such a vital process that it must be under tight control through regulation of uncoupling protein activity. This new area of investigation needs to be addressed if we want to understand their physiological role.

### G Leptin and Resting Energy Expenditure

Leptin, the product of the *ob* gene, is mainly synthesized in adipose tissue and released into the circulation. It represents an afferent hormonal signal to the hypothalamus where it acts on specific receptors and induces a decrease in appetite and an increase in energy expenditure in rodents. In humans, it is likely that leptin decreases appetite, but a role in the control of resting energy expenditure is not established.

Human studies investigating the relationship between serum leptin concentrations and energy expenditure have yielded inconsistent results. Several studies showed that serum leptin concentrations were not related to resting energy expenditure (48–50). By contrast, Jorgensen et al. (51) reported that in men, serum leptin levels were a strong determinant of resting metabolic rate (RMR). The body composition of the individuals studied may, however, account for an apparent effect of leptin on energy expenditure. Fat mass is strongly related to serum leptin concentrations, and, besides fat-free mass, fat mass is also a predictor of RMR. Therefore, multiple regression analysis should be carried out to adjust RMR for FFM and fat mass, before concluding that leptin stimulates RMR. In a recent study in a free-living elderly population, Neuhäuser-Berthold et al. (52) clearly showed that leptin was not a significant predictor of RMR,

when the effects of FFM and fat mass on RMR are taken into account.

In conclusion, in humans, leptin is probably not involved in the regulation of RMR. In rats, leptin acting on hypothalamic receptors stimulates the CRH pathway which induces a stimulation of sympathetic activity and activates brown adipose tissue metabolism through adrenergic  $\beta_3$  receptors (53). The latter tissue being virtually absent in adult humans, this may explain why leptin has no effect on resting energy expenditure.

## III THERMIC EFFECT OF FOOD IN HUMANS

The energy expenditure increases significantly after a meal, which has first been attributed to the intake of protein under the term of “specific dynamic action.” It was subsequently recognized that not only protein intake, but also carbohydrate and, to a lesser extent, fat intake, stimulate energy expenditure. This effect is nowadays called dietary-induced thermogenesis, or the thermic effect of food.

The thermic effect of food is mainly due to the energy cost of nutrient absorption, processing, and storage. The total thermic effect of food over 24 hr represents ~10% of the total energy expenditure in sedentary subjects.

### A Techniques for Measurement of the Thermic Effect of Food

The best technique to assess the thermic effect of a meal is to measure the energy expenditure following a meal during 3–5 hr and to compare the values with a control test during the same period of time, after a zero-energy drink is given. Alternatively, one often measures resting energy expenditure in a postabsorptive subject during 1 hr to get a stable baseline. Thereafter, a meal is given to the subject and energy expenditure is continuously measured with a ventilated hood during 3–5 hr. The area under the curve over the baseline (considered a constant reference value) represents the thermic effect of the meal. It is important that the period of measurement be of sufficient duration to include the entire thermogenic response (54).

### B Effect of Energy Intake and Dietary Composition on the Thermic Effect of Food

The thermic effect of nutrients mainly depends on the energy costs of processing and/or storing the nutrient.

Expressed in percent of the energy content of the nutrient, values of 8%, 2%, 20–30%, and 22% have been reported for glucose, fat, protein, and ethanol, respectively (9,55,56).

Glucose-induced thermogenesis mainly results from the cost of glycogen synthesis and substrate cycling (9). Glucose storage as glycogen requires 2 mol ATP/mol. In comparison with the 38 mol ATP produced on complete oxidation of glucose, the energy cost of glucose storage as glycogen corresponds to 5% (or 2/38) of the energy content of glucose stored. Cycling of glucose to glucose-6-phosphate and back to glucose, to fructose -1,6-diphosphate and back to glucose-6-phosphate, or to lactate and back to glucose, is occurring at variable rates and are energy-requiring processes which may increase the thermic effect of carbohydrates.

The thermic effect of dietary fat is very small; an increase of 2% of its energy content has been described during infusion of an emulsion of triglyceride (57). This slight increase in energy expenditure is explained by the ATP consumption in the process of free fatty acid reesterification to triglyceride. As a consequence, the dietary energy of fat is used very efficiently.

The thermic effect of proteins is the highest of all nutrients (20–30% of the energy content of proteins). Ingested proteins are degraded in the gut into amino acids. After absorption, amino acids are deaminated, their amino group transferred to urea, and their carbon skeleton converted to glucose. These biochemical processes require the consumption of energy amounting to ~25% of the energy content of amino acids. The second pathway of amino acid metabolism is protein synthesis. The energy expended for the synthesis of the peptide bonds also represents ~25% of the energy content of amino acids. Therefore, irrespective of their metabolic pathway, the thermogenesis induced after amino acids absorption represents ~25% of their energy content.

The thermic effect of ethanol amounts to ~22% of its energy content (56). The acute effects of ethanol ingestion include a decrease in the plasma free fatty acids level and a change in the cellular redox state in the liver cells, with an inhibition of lipid oxidation.

### **C Effect of Gender, Menstrual Cycle, and Age on the Thermic Effect of Food**

The thermic effect of food is apparently not influenced by gender. More than a decade ago, we observed that the thermic effect of an oral load of glucose was negatively correlated with age (58). The effects of age on the thermic effect of food are entirely explained by the

decrease in fat-free mass with age (59). Thus, when the thermic effect of food is corrected for the fat-free mass, both young and elderly subjects have similar values (59). A clear effect of menstrual cycle has not been observed since the thermic effect of food was found blunted during the luteal phase (60) or unchanged (61).

### **D Effect of Body Composition and Nutritional Status on the Thermic Effect of Food**

The effect of body composition on the thermic effect of food has been much studied. The hypothesis of a “thrifty gene,” a genetic propensity to increase the efficiency of energy utilization has been proposed to explain how humans have survived during periods of famine over the millions of years of evolution. According to this hypothesis, there has been a strong selective pressure to eliminate individuals with a low metabolic efficiency, whereas those with a thrifty gene have had greater chance of survival thanks to a more efficient energy metabolism. When exposed to conditions of plenty, those with a thrifty gene have an increased risk to become obese.

In support of this hypothesis, it has been reported that thermogenesis is decreased in most obese individuals (62). The reduction of postprandial thermogenesis in obesity is related to the degree of insulin resistance, which may be influenced by a low sympathetic activity (63). Thermogenesis is the energy expenditure above basal metabolic rate due to food intake, cold exposure, thermogenic agents, and psychological influences. The most important factor that stimulates thermogenesis is food intake (9). However, note that caffeine (64) and nicotine (65) are thermogenic agents that stimulate energy expenditure. Cold exposure does not play a significant role in stimulating energy expenditure under usual life conditions (66). Humans avoid cold exposure by wearing clothes and maintaining room temperature in the comfort zone. Dietary thermogenesis includes two components: the “obligatory” costs of digesting, absorbing, processing, and storing the nutrients, and a “facultative” component. The facultative component of thermogenesis depends on the sympathetic nervous system (67). Carbohydrate overfeeding induces a sustained rise of urinary norepinephrine (68), and infusions of glucose and insulin increase plasma norepinephrine levels (69). Additional evidence of the activation of the sympathetic nervous system after carbohydrate infusion is the reduction of the glucose-induced thermogenic response by  $\beta$ -adrenergic blockade with propranolol (70).

The possible contribution of a thermogenic defect in the etiology of obesity is controversial. The thermogenic responses to glucose or meal ingestion are either decreased (71–80) or unaltered (81–87) in obese subjects. The thermic effect of infused insulin-glucose was found to be reduced in insulin resistant and non-insulin-dependent diabetes mellitus (NIDDM) obese patients (88–90). The thermic effect of insulin-glucose was found to be proportional to the rate of glucose storage. This concept is supported by Ravussin et al. (91), who showed a similar thermic effect of glucose in lean and obese subjects when they were infused at the rate of insulin needed to obtain a predetermined glucose uptake. Obese subjects had to be infused with a larger rate of insulin infusion in order to get the same rate of glucose uptake as that of lean subjects. With a similar rate of glucose uptake, the thermogenic response was the same in lean and obese subjects. It can be concluded that obese subjects with impaired glucose tolerance and NIDDM obese patients have a decreased rate of glucose storage after a meal (or a glucose load) accompanied by a reduced rate of storage of glucose as glycogen in muscles, with an economy of energy expenditure.

It is interesting to evaluate the possible role of a thermogenic defect in the weight gain that occurs in most patients after cessation of an hypocaloric therapy. We calculated that a thermogenic defect can account for a maximal energy saving of approximately 125 kcal/d. Because the increase in body weight is accompanied by a rise in energy expenditure of  $\sim 25$  kcal/d/kg weight gain, it can be calculated that a weight gain of 5 kg (i.e., a rise in energy expenditure of  $\sim 125$  kcal/day) completely offsets the effect of the thermogenic defect (92). Therefore, a thermogenic defect is a factor that contributes to the weight gain after cessation of dietary therapy but it has a modest effect (92). It is likely that an abnormality in the control of food intake plays the most important role in the development of obesity or in relapse of body weight gain after an hypocaloric diet. Obese individuals, even those with a low basal metabolic rate per unit lean body mass, expend more energy than lean sedentary individuals (93). Thus, the important conclusion is that the concept of “small eaters” who remain obese with daily energy intake less than 1800 kcal/d is certainly wrong.

#### **E Control of the Thermic Effect of Food by the Autonomic Nervous System and by Hormones**

The sympathetic nervous system (SNS) plays a role in the control of energy expenditure. As already described, the thermogenic response to food ingestion

includes a facultative component that depends on the activity of the SNS (70). Recent evidence shows that oral (94) or intravenous (95) glucose administration stimulates muscle sympathetic nerve activity (MSNA). Increased activity of the SNS may contribute to the thermic effect of food since  $\beta$ -adrenergic blockade with propranolol decreases glucose-induced thermogenesis (70,96). However, the metabolic effects of catecholamines released at sympathetic nerve endings or by the adrenal medulla remain unclear (97).

Since the parasympathetic nervous system is involved in the cephalic phase of insulin secretion at the beginning of a meal (98), a role for this system has also been investigated in the control of the thermic effect of food (99). Cholinergic blockade with atropine decreases the thermic effect of a meal (99). This effect can be explained in part by the fact that atropine slows gastric emptying and reduces intestinal motility. Thus, the thermogenic mechanisms which are dependent on the parasympathetic nervous system may be related to intestinal absorption and the subsequent rate of storage of the absorbed nutrients.

The main hormone involved in the thermic effect of a meal is insulin. There is a reduced thermogenic response to a meal in obese subjects with insulin resistance and in obese NIDDM patients. Thus, either insulin resistance or a relative defect in insulin secretion (or both) induces a reduced glucose-induced thermogenesis. The latter is due in part to an impaired rate of glucose storage as glycogen in muscles; whether a reduced activation of the SNS plays a role is still unknown.

#### **F Familial and Genetic Effects on Thermic Effect of Food**

Genetic factors may contribute to the interindividual differences observed in the components of energy expenditure. Studies on the genetic effect of energy expenditure associated with the thermic effect of food are limited. Bouchard et al. (36) measured the thermic effect of a 1000-kcal meal during 4 hr in 21 pairs of dizygotic twins and 37 pairs of monozygotic twins, as well as in 31 parent-offspring pairs. The results suggest a genetic effect of less than one-third of the total thermic effect of food. Expressed in absolute values, the standard deviation of the thermic effect of food over 4 hr reached  $\sim 20$  kcal, and the 95% confidence intervals were therefore  $\pm 40$  kcal, or  $\pm 4\%$  of the energy intake. These data confirm that the variance of the thermic effect of food between individuals represents a relatively small proportion of the total energy turnover. By comparison, the 95% confidence intervals

were  $\sim \pm 250$  kcal/day for resting energy expenditure, or  $\pm 10\%$  of total energy expenditure.

#### IV COMPONENTS OF TOTAL ENERGY EXPENDITURE IN THE LEAN AND OBESE STATES

##### A Absolute Versus Relative Values

It has been customary to distinguish among the following different components of total energy expenditure (TEE): basal metabolic rate, postprandial thermogenesis (or thermic effect of food), and physical activity. This partition is important since the reasons for an abnormal 24-hr energy expenditure can be ascribed to a combination of abnormal subcomponents. As defined in preceding sections, the basal metabolic rate represents the energy expended in resting conditions under fasting state and comfortable environmental conditions; the thermic effect of food represents the net increase in postabsorptive resting metabolic rate in response to the ingestion of a meal or to an increase in total food intake (diet induced thermogenesis). In addition, extra non-meal-mediated thermogenic stimuli may occur owing to cold or heat exposure, as well as psychological factors (emotion or stress) or results from the administration of hormones and drugs. However, physical activity is the most variable (and hence least predictable) component of total energy expenditure. In contrast to the other components, it can be voluntarily modified by the behavior of the subject. In absolute terms, the total energy expenditure of the obese has been shown to be greater than that of lean individuals, both in the confinement of a respiration chamber (13,62,85) and in free-living conditions (100).

The relative rate of TEE can be expressed as a multiple of some baseline values such as RMR. This approach has been used by an international expert committee for calculating the energy requirement in the so called "factorial" method (101). Since both the RMR and TEE of obese subjects are greater in absolute value, it seems of interest to calculate the ratio between the latter and the former. This provides a rough index of physical activity ("physical activity level; PAL), but the contribution of the thermic effect of foods represents a small confounding factor. Since the energy cost for a given activity is proportional to body weight, in particular for weight-bearing activities, the absolute energy expenditure during weight bearing activity will be linearly related to body weight (102). A flat (or a negative) relationship between the energy expenditure due to

physical activity and the degree of obesity would indicate that the greater absolute cost of physical activity among obese subjects is largely offset by the depressed activity level. A study by Rising et al. (103) has shown that obesity was associated with lower levels of physical activity. The key question is to know whether a low level of physical activity is the *consequence* or the *cause* of obesity, or both.

Normalization of total energy expenditure in the obese appears to be difficult since the RMR is proportional to FFM (and fat mass) whereas the energy expenditure related physical activity is proportional to body weight. Although there is a statistical bias in normalizing the TEE by RMR (104), it seems to be a reasonable way (as compared to other alternatives) to express as such the free-living energy expenditure. The fact that both the absolute RMR and the energy cost for a given activity are greater in the obese explain why the TEE expressed in relative value (TEE/RMR) is not expected to be dramatically different from that observed in a nonobese subject. In this context, it seems of interest to review the magnitude of the ratio TEE/RMR in nonobese and obese adult subjects. Table 3 shows an overview of different experimental studies recently published in the literature (105–112). Globally considered, there is no strong evidence that the ratio TEE/RMR is systematically lower in obese individuals than in lean subjects, although the variations among and within studies was substantial (Table 3). This confirms our previous results in the respiration chamber (13).

Compilations of total daily energy expenditure results (using a meta-analysis approach) in individuals of various body weight and gender have been made by Schulz and Schoeller (113) and Carpenter et al. (104). In all these studies, energy expenditure was assessed by the doubly labeled water technique. In the former study (113), it was found that the increased weight of men (but not of women) was associated with a tendency for the TEE/RMR ratio to be lower, corroborating the notion that obesity tends to depress physical activity in obese men. This tendency was confirmed in a subsequent meta-analysis by Prentice et al. (109).

Because of the increase in prevalence and incidence of childhood obesity, it seems also important to study the energy metabolism in children as they grow through puberty in order to initiate early therapeutic intervention and prevent subsequent obesity in adults. Blunted physical activity due to a greater placidity and sedentary life-style are associated with low TEE (114–116). A classic study by Dietz et al. (117) has shown that the amount of time dedicated to watch television

was related to the degree of obesity in childhood. The relationship between a low level of physical activity and the accumulation of body fat in children has been the subject of a number of studies in both infants and children of Caucasian and Pima Indian origin (114, 118,119). The classic study by Roberts et al. (119) suggested that infants who were overweight at 1 year of age had a low total energy expenditure 9 months earlier (i.e., at 3 months of age) compared with a control group of children. The blunted rate of energy expenditure can be considered as one of the causal factors since at the time the infants were measured (3 months) they were not overweight.

Although the total daily energy expenditure in free-living condition in obese children is, expressed in absolute value, either greater than (120) or similar to (121) a matched group of lean children, this does not imply that the obese children have the same level of physical activity since the same type of activity will involve a greater energy cost in obese children. Taken together, these studies suggest that a reduced physical activity-related energy expenditure constitutes an important factor in the etiology of the subsequent weight gain. The study of Davies et al. (122) has shown a negative association between the level of physical activity as determined by the ratio between TEE and resting metabolic rate (physical activity level) and the percentage body fat in a sample of 77 boys and girls. A review

on the available measures of physical activity indexes has just been published (123).

## B Effect of Weight Loss on Energy Expenditure

When significant weight loss occurs, energy expenditure decreases, whereas weight gain leads to a rise in energy expenditure. This will depend on the respective effect of the individual factors influencing the three components of TEE: resting energy expenditure will decrease as a function of the loss of FFM; the absolute thermic effect of food will be lower as a result of the restricted dietary intake; and, for a given rate of physical activity, the absolute energy expenditure due to physical activity will drop because of the lower body size. In a prospective study of weight loss and relapse in body weight gain, we found that the rate of TEE and RMR essentially followed the change in body weight and body composition. The progressively reduced (or increased) energy expenditure accompanying weight loss (or weight gain) constitutes one of the major factors that explain the decrease in the rate of weight loss (or weight gain) with time. Another factor is the change in dietary compliance during dieting, which seems to be an individual characteristic.

Finally, it should be recalled that the compensatory energetic processes mentioned above tend to jeopardize the persistence of the altered body weight in obese

individuals, accounting for the generally poor long-term efficacy of obesity treatments. (124).

### I ENERGY EXPENDITURE DURING PHYSICAL ACTIVITY

#### A Human Energy Balance

Biological entities obey physical laws, and, in this regard, humans and other mammals obey the laws of thermodynamics. Body energy stores can only increase and obesity can only occur when food intake exceeds energy expenditure (or metabolic rate). Similarly, energy stores can only be depleted when energy expenditure exceeds food intake. Thus, the balance between food intake and energy expenditure determines the body's energy stores. The quantity of energy stored by the human body is impressive; lean individuals store 2–3 months of their energy needs in adipose tissue whereas obese persons can carry a year's worth of their energy needs. The cumulative impact of energy imbalance over months and years can result in the development of obesity. The factors that regulate appetite and food intake are discussed elsewhere. In this chapter we will discuss the importance of physical activity as a component of energy expenditure.

#### B Components of Energy Expenditure

There are three principal components to energy expenditure in humans: basal metabolic rate, thermic effect of food, and the energy expenditure of physical activity (activity thermogenesis). Basal metabolic rate is the energy expended when an individual is lying at complete rest, in the morning, after sleep, in the postabsorptive state. In individuals with sedentary occupations basal metabolic rate accounts for ~60% of total daily energy expenditure. About 75% of the variability in basal metabolic rate is predicted by lean body mass within and across species (1,2). Resting energy expenditure, in general, is within 10% of basal metabolic rate and is measured in subjects at complete rest in the postabsorptive state. The second component of energy expenditure is the thermic effect of food (3–6). This is the increase in energy expenditure associated with the digestion, absorption, and storage of food and accounts for ~10% of total daily energy expenditure; many believe there to be facultative (adaptive) as well as fixed components. The third component of energy expenditure is

the energy expenditure of physical activity, "activity thermogenesis." There are additional components of energy expenditure that may contribute to the whole, such as the energetic costs of altered temperature, medications, and emotion. Each of these components of energy expenditure is highly variable, and the sum effect of these variances determines the variability in daily energy expenditure between individuals.

It is likely that activity thermogenesis contributes substantially to the inter- and intraperson variability in energy expenditure. If three-quarters of the variance of resting energy expenditure is accounted for by variance in lean body mass, and if the thermic effect of food represents 10% of total energy expenditure, then the majority of the variance in total energy expenditure that occurs independent of body weight must be accounted for by the variance in physical activity. Evidence indeed suggests that this is so. The range of activity thermogenesis is wide, ranging from ~15% of total daily energy expenditure in very sedentary individuals to 50% or more of total daily energy expenditure in highly active individuals (7,8). Because this component of energy expenditure is the most variable component of energy expenditure, both within and between subjects (9), its potential role in body weight regulation and in the etiology of obesity deserves close examination. For example, Dauncey (8) estimates that differences in minor activity throughout the day can account for differences of 20% in 24-hr energy expenditure. Such differences, if not compensated for by changes in energy intake, can lead to significant changes in body weight and/or body composition.

Activity thermogenesis can be readily divided into that associated with purposeful exercise and that associated with nonexercise activities, such as the activities of daily living. Exercise is exertion for the specific purpose of physical fitness. Nonexercise activities include the myriad of activities of daily living that are not undertaken as purposeful exercise; they include maintaining posture, walking from the bus stop to work, tapping one's foot or hand while talking, and cleaning the house. The energy expenditure associated with each activity is the product of the time spent performing the activity and the energy cost of that activity per unit time. Thus, to assess activity thermogenesis as a whole, one needs to define each exercise and nonexercise task an individual performs, the time engaged in each activity, and the energy cost of each activity. The ability to do this accurately in free-living humans is technically demanding and is why the importance of activity thermogenesis in energy balance and obesity has been difficult to quantify and define.

In this chapter we will discuss activity thermogenesis, how it is measured, its components, and the impact of activity thermogenesis on other components of energy expenditure and energy balance as a whole.

## II METHODOLOGY

Before we can begin to understand the role of activity thermogenesis in energy balance and the pathogenesis of obesity, we must first quantify the nature and duration of exercise and nonexercise activities.

### A Quantifying the Nature and Duration of Exercise

A series of tools has been used and, in some cases, validated to quantifying exercise. One approach has been to employ prospective methods (10). Prospective measures include the use of diaries or other recording media (e.g., handheld tape machine) to have subjects record the nature and intensity of exercise performed over a defined time period. The disadvantages of this approach are the reliance on the subjects to record data precisely and the subjective nature of the intensity determinations. An alternative or complementary method for prospective data collection is to record physiological variables, such as pulse rate or respiration, over the period of interest (11). For example, a subject is fitted with a pulse recorder (12) that records along with a time stamp. In this fashion, objective information is gained regarding the duration over which exercise is likely to have been performed (i.e., the time periods during which pulse exceeded a predefined cutoff). The disadvantage of this approach is that no information is gained regarding the nature or intensity of exercise. Studies have repeatedly demonstrated that the magnitude of the change in pulse does not reflect the energetic cost of the exercise performed because heart rate and stroke volume do not change linearly with exercise intensity (13,14).

Retrospective approaches for quantifying exercise have been widely used. A variety of questionnaires (15–17) have been devised that ask subjects to recall their habitual levels and intensities of exercise or to recollect exercise bouts over a defined period. These assessments are often relatively straightforward to perform (many using self-administered questionnaires), rapid, and inexpensive. This approach enables large groups of subjects to be studied. The disadvantage of retrospective surveys of exercise is the inability to verify the precision of the data. On balance, the vali-

dated tools are applicable for group comparisons either in cross-sections or longitudinal studies.

## **B Quantifying the Nature and Duration of Nonexercise Activities**

Nonexercise activities are enormously varied and include body postures, locomotion, fidgeting, talking, and brushing hair. Quantifying nonexercise activity is extremely taxing, and little information is available about the energy expended in these activities. Furthermore, the physical activities can be expressed in a variety of units; as the time period of activity (hours, minutes), as units of movements (counts), or even as a numerical score derived from responses to a questionnaire. Activity can also be defined as an overt intentional behavior (e.g., the number of social contacts).

### **1 Activity Recall and Time and Motion Studies**

Nonspecific information about habitual and occupational activity can be obtained using questionnaires, interviews, or time-and-motion studies. Predictably, substantial errors are introduced through inaccurate recall and inadequate data recording. These approaches can be used, however, for following trends in certain activities, particularly with relation to occupational practices (18).

### **2 Kinematic Measurements**

In kinematic measurements, a subject's movements are quantified. Some techniques are specific for confined spaces such as radar tracking and cinephotography (19,20). Other techniques have been used in free-living individuals and generally focus on pedometers and accelerometers of varying sophistication. Pedometers typically detect the displacement of a subject with each stride. However, pedometers tend to lack sensitivity because they do not quantify stride length or total body displacement and overall, therefore, become poor predictors of total activity thermogenesis (21) although potentially of value for quantifying walking (e.g., to determine compliance with a walking program). Accelerometers detect body displacement electronically with varying degrees of sensitivity—uniaxial accelerometers in one axis and triaxial accelerometers in three axes. Portable uniaxial accelerometer units have been widely used to detect physical activity (22–24). Careful evaluation demonstrates that these instruments are not sufficiently sensitive to quantify the physical activity of a given free-living subject but rather they are more valuable for comparing activity levels between groups of

subjects. Greater precision has been obtained using triaxial accelerometers (25–27). In free-living subjects, data from these devices correlate well with total daily energy expenditure, measured using doubly labeled water divided by basal metabolic rate (28). The utility of motion tracking using approaches such as Global Positioning Systems has not been fully defined for human studies.

Thus, methods are available for quantifying the amounts of exercise and nonexercise activities that an individual performs. Because of the variable precision of these measures, caution is recommended in applying these techniques for measurements and when interpreting reported studies.

## **C Quantifying the Energy Cost of Exercise and Nonexercise Activities**

The energy costs of specific exercise and nonexercise activities are readily measurable. The technique most often used is indirect calorimetry, whereby oxygen consumption, carbon dioxide production, or both of these variables are measured before and during the activity of interest. Energy expenditure is then calculated by means of established formula (29,30).

Indirect calorimeters vary in sophistication and cost (31). In the laboratory, ventilated open-circuit calorimeters are most often used. Here expired air is collected by means of a mouthpiece, a mask, or a hood or from a sealed chamber (32,33). The air is then mixed, the rate of flow is measured, and oxygen and carbon dioxide concentrations are determined. Measurements to within 1% of chemical standards can be achieved using these devices. In the field, Douglas bags or portable expiratory open circuit calorimeters are most often used. The Douglas bag (34–37) comprises a polyvinyl chloride (or other leakproof material) bag of ~100–150 L (38). After collection of the expired air, the volume of expired air in the bag is measured and a sample analyzed to determine oxygen and/or carbon dioxide concentrations. The technique is highly operator dependent and under optimal conditions the error of energy expenditure measurements undertaken with Douglas bags can be small (< 3%). A variety of portable expiratory open-circuit systems have been devised (39–42). In most, expiratory flow is measured, as are expired oxygen and/or carbon dioxide concentrations. Although less precise than laboratory based instruments, their flexibility allows data to be collected on daily physical activities in the most germane setting.

The techniques for measuring the energy costs of exercise and nonexercise activities are readily defined

and, when carefully executed, provide reliable and precise measurements in both the laboratory and field settings.

## D Quantifying Activity Thermogenesis

Little information is available regarding the time period of measurement needed to gain a representative assessment of physical activity. We estimate that approximately 7 days of measurement are likely to provide a representative assessment of activity thermogenesis for a given 3- or 4-month block of time. Such 7-day measurements can be repeated to understand the importance of season and changing occupational roles.

There are three principal approaches to estimating activity thermogenesis. The first is to measure it directly in a chamber-style calorimeter. Although this is the only means of directly measuring activity thermogenesis, the approach is enormously limited because subjects are confined to a small (e.g., 12 m<sup>2</sup>) room for the measurement duration and so cannot perform their normal daily activities (9,32). Measurement of activity thermogenesis in free-living individuals is more challenging. Broadly, investigators have either tried to sum the energetic equivalents for each activity a subject undertakes, termed the factorial method (39,43,44), or total daily, free-living energy expenditure is measured using doubly labeled water (45) with no attempt made to ascertain the constituents of activity thermogenesis.

Prentice et al. (46) have noted the importance of considering differences in body size when interpreting measurements of physical activity. Caution must be used when making comparisons of energy expended in physical activity between individuals who differ markedly in body size. The physical activity level (PAL) is a calculation often used to express activity thermogenesis values relative to body size. The PAL is calculated as total daily energy expenditure (TEE) divided by RMR. For sedentary subjects the PAL is  $\sim 1.5$ . This value can increase to around 3.5–4.5 under extreme exercise conditions. Alternatively, activity thermogenesis can be calculated from:

$$\begin{aligned} \text{Activity thermogenesis} &= \text{total energy expenditure} \\ &\quad - (\text{basal metabolic rate} \\ &\quad + \text{thermic effect of food}) \end{aligned}$$

Here, thermic effect of food is often not measured but assumed to equal 10% of total energy expenditure.

## 1 Activity Logs and the Factorial Method

This is a frequently used approach for estimating activity thermogenesis in free-living individuals. First, a subject's physical activities are logged over the time period of interest (e.g., 1 week). The energy equivalent of each of these activities is measured or estimated using a calorimeter or tables, respectively (39,43,44). The time spent in each activity is then multiplied by the energy equivalent for that activity. These values are then summed to derive an estimate of activity thermogenesis.

Errors for the factorial method may first result from inaccurate recording of activities and, secondly, from inaccurate determinations of the energy costs of the activities. To log activity, subjects are often asked to record in a diary the nature and amount of time spent performing each of their activities throughout the day (47). This has several limitations: subjects may be illiterate or anumerate, may report their activities inaccurately or incompletely, and/or may alter their normal activity patterns during periods of assessment. To limit these sources of error, one approach is to have trained enumerators follow subjects and objectively record the subject's activities (18). This is time-consuming and expensive but potentially a valuable source of accurate and objective data.

Newer image gathering technologies may be useful in the future for this purpose. To determine the energy costs of physical activities, standard tables are often used. However, these may introduce substantial (albeit systematic) errors. First, the tables may not include the precise activity the subject performed. Second, the energy cost for a given activity is highly variable between subjects even independent of gender. Third, calorimeter methods for measuring the energy costs of activities have not been standardized between investigators so that precision and accuracy of data in the activity tables cannot always be assured.

To limit these errors, the energy costs of each or most of the activities that the subjects of interest perform can be measured using calorimeters, as described above. At best, the energy costs for each subject's activities would be measured but clearly this is rarely practical except for small studies. In general, population-, gender-, age-specific group means for the majority of the studied subjects activities represents a standard that is worth achieving where optimum precision is warranted.

## 2 Doubly Labeled Water (DLW)

In the doubly labeled water method (45,48–52), both the hydrogen and oxygen of water are labeled or “tagged” using stable, nonradioactive isotopes (D<sub>2</sub>O<sup>18</sup>). Elimina-

tion of administered  $D_2O^{18}$  may be used to estimate carbon dioxide production and energy expenditure.

The principle of this technique is as follows. In body water, the  $O_2$  of expired  $CO_2$  is in equilibrium with the  $O_2$ :

Thus, if the  $O_2$  in body water is tagged with the tracer  $O^{18}$ , the label will distribute not only in body water but also in circulating  $H_2CO_3$  and in expired  $CO_2$ . Over time the concentration of the  $O_2$  label in body water will decrease as  $CO_2$  is expired and body water is lost in urine, perspiration, and respiration. If the  $H_2$  in body water is tagged with the tracer  $D_2$ , the label will distribute solely in the circulating  $H_2O$  and  $H_2CO_3$ . Over time, the concentration of the  $H_2$  label will decrease, as body water is lost (some of the hydrogen can become partitioned into body protein or fat, however). Thus, if both the  $O_2$  and  $H_2$  in body water are tagged, with known amounts of tracers at the same time, the differences in the elimination rates of the  $O_2$  and  $H_2$  tracers will represent the elimination rate of  $CO_2$ .

Subjects are usually given DLW orally after baseline samples of urine, saliva, or blood have been collected. Time is allowed for complete mixing of isotopes to occur within the body water space and then samples of urine, saliva, or blood are collected over 7–21 days. These samples are used for measurements of  $D_2$  and  $O^{18}$  enrichments using mass spectroscopy. Changes in  $D_2$  and  $O^{18}$  concentrations in body water are then calculated over time, and  $CO_2$  production and energy expenditure are calculated. Energy expenditure can be measured over 7–21 days using this technique with an error of  $\sim 6$ –8% (52). This error can be decreased to a small degree, by collecting samples repeatedly over the measurement period rather than by collecting samples only before and after the measurement period.

Doubly labeled water allows total energy expenditure to be measured to within  $\sim 6$ –8% of actual. Basal metabolic rate can be measured to within 1% of actual, so the cumulative error for measurements of PAL is  $\sim 7$ %. This is impressive considering the measurements are performed in completely free-living individuals. A major limitation of this approach is, however, that no information is gleaned regarding the components of physical activity and how these contribute relative to others. It can thus be difficult to discriminate the impact of exercise from nonexercise or to ascertain the importance of the different components of nonexercise activity thermogenesis (NEAT).

It is thereby possible to measure activity thermogenesis. No approach is ideal, but these available technologies readily enable hypotheses to be addressed regarding activity thermogenesis and its role in energy balance in free-living individuals.

### III AMOUNT OF PHYSICAL ACTIVITY HUMANS PERFORM

There are several sources of data that allow information to be gleaned regarding the quantities of exercise and nonexercise activities that humans perform.

#### A Amount of Exercise Humans Perform

Several comprehensive surveys have provided data on exercise levels in adults in the United States, a population where obesity is epidemic: the National Health Interview Survey (53), the Behavioral Risk Factor Surveillance System (54), and the Third National Health and Nutrition Examination Survey (55). Approximately 22–29% of adults report no participation in leisure time physical activity within 2–4 weeks of the point of survey. Individuals at greater risk for undertaking no exercise are those who are female, black or Hispanic, older, less educated, and receiving lower income. About 20–24% of individuals participate in regular sustained physical activity (five or more times a week for  $>30$  min duration per occasion). The individuals most likely to participate in regular exercise are those who were male, white, younger, more educated, and receiving greater income. The most common forms of exercise are (in descending order) walking for purposeful exercise, gardening or yardwork, stretching exercises, and bicycling. More worrisome still are U.S. survey data derived from children. A quarter of U.S. individuals aged 12–21 years report no exercise, and participation in all types of physical activity declines toward adulthood. These data are echoed by others from developed countries.

#### B Amount of Nonexercise Activities Humans Perform

Because, as noted above, the variety of nonexercise activity is so enormous and the ability to quantify it so poor, it is very difficult to gain a true estimate of free-living individuals' nonexercise activities. Some of the better-quality data have been derived from approaches where trained enumerators follow individuals and record their physical activities at short time intervals.

These data allow precise determination of the range and type of physical activities performed by specific populations (45,49,56). What transpires from reviewing these surveys is, not surprisingly, that an individual's cultural environment defines the vast majority of the variability in the amount of nonexercise activity performed. The two key components of this cultural environment appear to be first the individual's occupation, and second the "sedentariness" of the indigenous population.

The occupational impact on nonexercise activity can be overt—for example, when comparing nonexercise activity between physical laborers and civil servants (57–59). More subtle occupational effects on physical activity include the impact of factors such as gender. For example, in many populations where women work both in home and out of the home, their cumulative work burden exceeds that of male cohabitants by several hours per day (56).

The importance of population sedentariness is well illustrated by studies of physical activity levels for individuals moving from agricultural communities to urban environments or of the effects of industrialization. In many populations where this has occurred, urbanization been associated with decreased physical activity and increased obesity. Sedentary cues are unmistakable in developed countries often through services designed to optimize convenience and throughput at the expense of necessitating locomotion. Examples include drive-through restaurants and banks, televisions, remote controls, escalators, motorized walkways and clothes washing machines. The sedentariness of a population is likely to be affected by a variety of specific factors that include genetics, age, gender, body composition, education, and season.

### 1 Variation Due to Genetic Background

It is likely that genetics play some role in determining the amount of physical activity performed. Data in support of this notion was reviewed by Bouchard et al. (60). Based on twin and family studies, the heritability for physical activity level has been estimated as between 29% and 62%. Analysis of self-reports of physical activity from the Finnish Twin Registry, consisting of 1537 monozygotic and 3057 dizygotic twins, estimated a 62% heritability level for age-adjusted physical activity (61). Analyses of self-reported physical activity from the Quebec Family Study, consisting of 1610 members of 375 families, showed a heritability level of 29% for habitual physical activity (62).

### 2 Variation Due to Age

Many datasets consistently show a decline in physical activity with aging (63–65), with the decline occurring in both men and women. However, some data suggest that during the period 1986–1990, activity levels decreased more in elderly subjects than in young adults (65).

### 3 Variation Due to Gender

Adult men and women in the United States report similar levels of aerobic and moderate physical activity (65,66). In other countries, such as Canada, England, and Australia, men report 1.5–3 times more aerobic or moderate activity than women (64,67,68). Women in the United States appear to have increased their physical activity more than men during the period 1986–1990 (65,66). In children, a consistent gender difference is found, with boys being more active than girls (69). Gender may influence physical activity in more subtle ways such as through the influence of culturally defined gender occupational roles.

### 4 Variation Due to Body Composition

There are substantial data to suggest that overweight individuals are less active than their lean counterparts (70–72). This appears to be true across all ages, for both genders, and for all ethnic groups. We cannot, however, conclude on the basis of available evidence that a low level of physical activity contributes to development of obesity. It is equally possible that development of obesity leads to a reduction in physical activity. Reduced activity may partly be balanced by increased energy cost of weightbearing activities. In fact, moving around with a higher body mass implies a higher energy cost.

### 5 Variation Due to Education

Groups with more education consistently report more leisure time physical activity than groups with less education. In the United States, highly educated groups are two to three times more likely to be active than those with less education (63,65,66).

### 6 Seasonal Variations in Physical Activity

Limited data are available regarding differences in amount of physical activity performed during different seasons. Data from Canada suggest wide differences in time spent in physical activity due to season. Time spent

in these activities was twice as high during the summer months as in the winter months (67).

#### IV ENERGY COST OF PHYSICAL ACTIVITIES

The other major determinant of activity thermogenesis is the efficiency with which exercise and nonexercise activities (i.e., work) are performed. Work efficiency can be defined as the amount of work performed divided by the energy expended in performing the work. While it is clear that work efficiency is not constant for all human subjects, the extent of individual differences and their importance in body weight regulation is unclear. Several studies have reported differences in work efficiency between groups of subjects, and these will be discussed below. It seems logical that differences in morphology/metabolism of skeletal muscle may play a role in determining work efficiency. Blei et al. (73), using  $^{31}\text{P}$  NMR spectroscopy, reported that human muscle varied nearly twofold in both energy cost per twitch (energy cost) and recovery time constants (oxidative capacity) across individuals.

##### A Data on the Metabolic Cost of Exercise

Since for the average adult the resting metabolic rate (RMR) is fairly close to 3.5 mL/kg min of oxygen, or 1 kcal/kg of body weight h, the energy cost of activities can be expressed as multiples of RMR and called METs (an abbreviation of “metabolic”). The use of METs is a simple approach to estimate energy expenditure, taking body weight into account. Ainsworth et al. (74) have published an extensive compendium of MET values of all type of activities. MET values provide an indication of intensity of physical activity and, when summed over time, can be used to compare level of physical activity between individuals.

The gross energy cost of exercise that can be maintained for more than a few minutes roughly varies between 2.0 METs (leisure walking) and 8.0 METs (running 5 mph). However, to expend more energy (e.g., 18 METs; running 10 mph) for a longer period of time, the aerobic fitness of an individual has to be far beyond the level that is observed in general population. An individual who has an aerobic fitness of 35 mL/kg min, which is the average for a normal weight 40-year-old female, is not able to expend more than 7 METs (corresponding to 70% of her  $\text{VO}_{2\text{max}}$ ) for

>30 min. A deterioration in aerobic fitness can thus reduce the ability to be active.

##### B Postexercise Energy Expenditure

Energy expenditure does not return to preexercise levels immediately upon cessation of the physical activity, and the period of increased energy expenditure following exercise is called excess postexercise energy expenditure. The factors that determine the extent to which postexercise energy expenditure occurs have not been clearly defined, leaving a controversy regarding the overall importance of postexercise energy expenditure for overall energy balance (75). Some have suggested energy expenditure can be elevated as long as 24 hr after a bout of exercise (76); others have suggested baseline energy expenditure is restored within a few minutes after exercise cessation (77). Further, it appears that the magnitude and duration of the postexercise increase in energy expenditure is related to the intensity and duration of the exercise bout, with longer, more intense exercise likely to produce a more significant post-exercise increase in energy expenditure (78). Over a 12-hr period excess postexercise energy expenditure has been found to vary between 24 kcal after 120 min cycling at 100 Watt and 157 kcal after cycling 80 min at 70%  $\text{VO}_{2\text{max}}$  (79). Compared to the energy expenditure during exercise itself, the postexercise increase above RMR is modest and has been found to increase energy expenditure by exercise by another 3–15%.

In a review of this phenomenon, Poehlman et al. (80) concluded that, from a practical point of view, an exercise prescription for the general public that consists of low (<50%  $\text{VO}_{2\text{max}}$ ) and moderate intensity (50–70%  $\text{VO}_{2\text{max}}$ ) would result in an extra postexercise energy expenditure of only 9–30 kcal per bout. It is unlikely that these differences will significantly influence body weight regulation. In this regard, it is questionable whether the moderate exercise usually prescribed for moderately obese humans is sufficient to produce appreciable postexercise increase in energy expenditure.

##### C Data on the Metabolic Cost of Nonexercise Activities

It has long been known that even trivial movement is associated with substantial deviation in energy expenditure above resting values. For example, even mastication is associated with deviations in energy expenditure of 20% above resting (81). Very low levels

of physical activity such as fidgeting can increase energy expenditure above resting levels by 20–40% (82). It is not surprising that ambulation whereby body weight is supported and translocated is associated with substantial excursions in energy expenditure (28). Even walking at 1 mph doubles energy expenditure and purposeful walking pace (2–3 mph) is associated with doubling or tripling of energy expenditure. When body translocation is logged using a triaxial accelerometer attached to the back, the output from this unit correlates with nonresting energy expenditure. This implies that ambulation is likely to have a profound influence on NEAT and most likely total energy expenditure in many individuals. The energy costs of a multitude of occupational and nonoccupational physical activities have been charted and tabulated in a series of publications (74). What is noteworthy is the manifold variance in the energy costs of occupational related activities ranging from <1 MET (e.g., typing) to 5–10 METs (e.g., wood cutting, harvesting, or physical construction).

#### **D Factors that Affect the Energy Costs of Physical Activities**

It is recognized that several factors affect the energetic efficiency of exercise and nonexercise activities.

##### **1 Body Weight/Body Composition**

It requires more energy to move a larger body mass, and several investigators (83–85) demonstrated that energy expended in physical activity during weightbearing physical activity increased with increasing body mass. It is important to take into account the greater cost of physical activity of a larger body mass when assessing differences in physical activity between obese and non obese subjects. An obese person who is slightly less active than a lean counterpart may expend as much or more total energy in physical activity.

It is less clear whether work efficiency varies with body composition, independently of body weight. Some studies (86–89) have found no differences in work efficiency between obese and nonobese subjects, while others (90,91) have found a greater work efficiency in the obese. Most studies not finding differences in work efficiency have used cycle ergometers with a moderate workload, while those finding differences have used cycle ergometers with heavy loads or treadmills. Work efficiency may vary with type and intensity of physical activity. There are some data suggesting that oxygen consumption increases more rapidly in obese than lean individuals as workload increases

(90). This would be consistent with a greater work efficiency in the obese.

##### **2 Effects of Changes in Body Weight/Body Composition**

Several studies have reported that efficiency of work is reduced following weight reduction. Foster et al. (92) measured the energy cost of walking in 11 obese women before weight loss and at 9 and 22 weeks after weight loss. They determined that the energy cost of walking (after controlling for loss of body weight) decreased substantially by 22 weeks after weight loss. They estimated that with a 20% loss of body weight, subjects would expend ~427 kJ/hr less during walking than before weight loss. Geissler et al. (93) compared energy expenditure during different physical activities and found that energy expenditure was 15% lower in the postobese than in controls across different activities. DeBoer (94) found that sleeping metabolic rate declined appropriately for the decline in fat-free mass (FFM) when obese subjects lost weight but that total energy expenditure declined more than expected for the change in FFM. Similar results were obtained by Leibel et al. (95), who speculate that an increased work efficiency may be partially responsible for weight regain following weight loss.

Alternatively, Froidevaux (96) measured the energy cost of walking in 10 moderately obese women before and after weight loss and during refeeding. Total energy expended during treadmill walking declined with weight loss, but was entirely explained by the decline in body mass. Net efficiency of walking did not change. Poole and Henson also found no change in efficiency of cycling after caloric restriction in moderately obese women (88). Weigle and Brunzell demonstrated that ~50% of the decline in energy expenditure with weight loss was eliminated when they replaced weight lost by energy restriction with external weight worn in a specially constructed vest (97). Thus, while it is clear that total energy expenditure declines with weight loss, the extent to which changes in work efficiency contribute to this decline is controversial.

##### **3 Role of Skeletal Muscle Metabolism in Determining Work Efficiency**

Differences in skeletal muscle morphology/metabolism have been suggested to play a role in differences in work efficiency. Henriksson (98) has suggested that changes in muscle morphology in response to energy restriction lead to changes in the relative proportion of type I versus type II fibers in human subjects. Some studies

suggest that type II fibers have a greater fuel economy than type I fibers (99,100). Since type II fibers appear to be better preserved during starvation than type I fibers (98), overall fuel economy and work efficiency may be increased following energy restriction and loss of body mass. However, a study on muscle fiber type before and after a 10.8-kg weight loss in obese females did not show any changes in the fiber type distribution (101).

The potential contribution of skeletal muscle differences to differences in work efficiency between weight stable lean and obese subjects is more controversial. Substantial data suggest that obese subjects oxidize proportionally more carbohydrate and less fat than lean subjects in response to perturbations in energy balance (102–104) and that differences in morphology/metabolism of skeletal muscle and sympathetic nervous system activity (105) may underlie some of the whole-body differences (104,106). However, it is not clear to what extent such differences contribute to differences in work efficiency. Further, such differences may arise both from genetic and environmental causes.

#### 4 Genetic Contributions to Work Efficiency

Very little information is available to allow estimation of the genetic contribution to differences in efficiency of work. Bouchard et al. (107) assessed the energy cost associated with common body postures (sitting, standing) and low-intensity activities (walking, stair climbing, etc.) in 22 pairs of dizygotic and 31 pairs of monozygotic twins. All subjects were classified as sedentary. A significant genetic effect for energy expenditure was found with activities from 50 to 150 watts even after correction for differences in body weight. No genetic effect was seen for activities requiring energy expenditure greater than six times resting energy expenditure.

#### 5 Effects of Age on Work Efficiency

Work efficiency may vary with age. For example, Villagra et al. (108) demonstrated that children are ~10% more energy efficient during squatting exercises than adults. There is little information available to evaluate the effects of aging in adults on work efficiency. Skeletal muscle mass is often lost as a subject ages, and if the loss involves a greater proportion of type I than type II fibers, work efficiency could increase with age.

#### 6 Effects of Exercise Training on Work Efficiency

If work efficiency varies as a function of exercise training, training induced effects in skeletal muscle could be important. Alterations in physical activity can alter the

fiber type proportions of skeletal muscle as well as induce significant changes in enzyme activities. Aerobic exercise training results primarily in the transformation of type IIb into type IIa fibers, while transformation of type II fibers into type I fibers is not common unless the exercise training has been extremely intense over a long period of time. Type I fibers have a greater mitochondrial density and are more oxidative and more fatigue-resistant than type IIb fibers. Type IIb fibers are glycolytic in nature with lower mitochondrial content and are more prone to fatigue. Type IIa fibers are intermediate in their mitochondrial content and, in humans, closely resemble type I fibers in oxidative capacity. However, an overlap of oxidative capacity exists between fiber types groups. Type I and type IIa fibers are more energy efficient than type IIb fibers, and the proportions of these fiber types will vary according to the type of exercise training performed. It has been shown that even independently of fiber type alterations, the activities of important enzymes in oxidative and glycolytic pathways can be modified as a result of exercise training, and can lead to improvements in metabolic efficiency.

Sharp et al. (109) found that there was not a significant relationship between  $\text{VO}_2\text{max}$  and activity thermogenesis in a group of men and women studied in a whole-room calorimeter. Cross-sectional studies indicate that training may increase the efficiency of the activity when being trained. Elite runners and cyclists have lower energy expenditure at a certain speed than not specifically trained individuals. Differences can be accounted for 15% (running) up to 50% (swimming) (110,111). Children have a higher energy cost calculated per kg body weight for the same activity than do adults.

#### 7 Effects of Gender on Work Efficiency

There are several reports that female athletes, unlike male athletes, are more energy efficient than their sedentary counterparts (112–114). There are reports in the literature for increased energy efficiency in female runners (112), dancers (113), and swimmers (114) as compared to sedentary females. However, most reports make conclusions regarding energetic efficiency based on indirect rather than direct measurements of energy intake and/or expenditure. For example, Mulligan et al. (112) concluded that female runners had increased energy efficiency since their self-reported energy intake was less than their estimated energy expenditure. In the few studies in which both intake and expenditure were measured directly, no evidence of increased energy efficiency was seen in female runners (115) or female

cyclists (116). Thus, the question of whether female athletes show a different energy efficiency than sedentary females is controversial. If this proves to be true, the extent to which such differences might be due to differences in work efficiency is unknown.

## V ACTIVITY THERMOGENESIS AND TOTAL DAILY ENERGY EXPENDITURE

Measurements of activity thermogenesis have provided insight into the energy needs of individuals and into the physiology of energy balance. In terms of understanding the energy needs of individuals, data on PAL values have provided information regarding the energy expenditure associated with different occupations and the impacts of culture, gender, and physical states such as pregnancy and lactation. This information is invaluable in terms of understanding the energy requirements of individuals. This information has also guided how statutory agencies have defined the energy needs of populations (117). What is becoming clear is that the greater the quality of data on activity thermogenesis for a given population, the better the estimates will be of that population's energy needs. With fast-advancing technologies that allow data from activity sensors to be combined with doubly labeled water, enormous advance in this arena is anticipated.

## VI SUBSTRATE OXIDATION DURING PHYSICAL ACTIVITY

Body weight regulation involves balancing total energy intake and expenditure. It also involves maintaining over time a balance between intake and oxidation of protein, carbohydrate, and fat. Thus, it is useful to consider factors that influence both the amount and composition of fuel used during physical activity. When assessing factors that influence substrate oxidation, it is important to consider influences both during performance of exercise and during the postexercise recovery period.

### A Characteristics of Physical Activity

Skeletal muscle tissue has the ability to convert chemical energy to mechanical energy required for physical activity using the myosin motor proteins as a lever arm to produce movement (118). The immediate source of chemical energy required for contraction is provided by the hydrolysis of adenosine triphosphate (ATP) catalyzed by myosin ATPase.

Intracellular ATP stores are small and can be depleted within seconds of maximal contraction if they are not adequately replenished. The ATP synthesis pathways include the phosphagen system and (anaerobic) glycolysis. The phosphagen system includes the breakdown of creatine phosphate (CrP) as well as the regeneration of ATP from ADP by the adenylate kinase reaction. The anaerobic glycolysis pathway allows a five to six times higher ATP synthesis, than the oxidative glycolysis of glucose. The rate by which ATP can be generated depends on the biochemical pathways that are followed as well as on the substrate source.

In Table 1, the high-energy phosphate (HEP) formation rates following the aerobic and/or anaerobic breakdown of carbohydrates and fat are given. The rate of HEP formation depends clearly on the type of oxidation (anaerobic > aerobic), locations of the fuel source (endogenous > bloodborne), as well as the fuel type (carbohydrate > fat). Based on the examples given in Table 1, it can be seen that the maximal rate of ATP synthesis from fat can provide only enough energy to sustain exercise at 55–70% of maximal oxygen intake ( $\text{VO}_2\text{max}$ ) depending on the training status. However, the rate of energy generated from carbohydrate, both anaerobic and aerobic, can provide enough energy to sustain exercise up to maximal level for a short period of time.

**Table 1** Maximum Rate of High-Energy Phosphate (HEP) Regeneration from Carbohydrate and Lipid Substrates Compared to Utilization of HEP During Various Types of Exercise

| Maximum rate of HEP regeneration |   |
|----------------------------------|---|
| Substrate utilized               | Max. rate of formation HEP<br>Mol HEP.min <sup>-1</sup> |
| Endogenous glycogen (anaerobic)  | 2.4   |
| Endogenous glycogen (aerobic)    | 1.0   |
| Bloodborne glucose (aerobic)     | 0.37  |
| Bloodborne fatty acids (aerobic) | 0.40  |
| Rate of HEP utilization          |   |
| Type of exercise                 | Rate of utilization                                     |
| Rest                             | 0.07  |
| Walking                          | 0.3   |
| 100 m sprint                     | 2.6   |
| 800 m sprint                     | 2.0   |

Source: Ref. 126.

During endurance moderate-intensity exercise ATP demands can be provided entirely by oxidative phosphorylation of both intramuscular and bloodborne carbohydrate and fat. Substrate oxidation during exercise is often estimated from the whole-body respiratory quotient (RQ), which provides an indication of the relative proportion of carbohydrate and fat being oxidized. In comparing RQ between exercise conditions, it is important to consider total energy expended as well as RQ. Especially at low-intensity exercise, a relatively high proportion of lipids are oxidized, mainly as a result of the preferential oxidation of free fatty acids in the type I fibers. For example, at 20%  $\text{VO}_2\text{max}$ , RQ is  $\sim 0.80$ , meaning that 62% of the local substrate utilization is derived from fat. At 80%  $\text{VO}_2\text{max}$ , more type II fibers are involved and RQ value is 0.9, leading to a contribution of fat oxidation of only 21%.

The relative contribution of fat and carbohydrate oxidation to total energy expenditure during exercise can vary enormously and strongly depends on exercise intensity, training status, and diet (119).

Quantifying the rates of utilization of the different substrate sources during exercise is of importance to gain more insight into the metabolic consequences of physical activity. It enables us to evaluate the effects of dietary and training interventions on a whole-body level, thereby also contributing to our understanding of the metabolic defect(s) associated with obesity and non-insulin-dependent diabetes mellitus (NIDDM), (120,121).

## 1 Exercise Intensity

While the intensity of exercise is the major determinant of amount of energy expenditure as well as substrate source, both the intensity and duration of exercise influence the source of fuel used for exercise (119).

Substrate utilization rates in relation to exercise intensity have been derived by Romijn et al. (122) using stable isotopes to estimate whole body oxidation rate of all endogenous substrate sources as a function of exercise intensity. In Figure 1, the endogenous substrate utilization during exercise at low (25%  $\text{VO}_2\text{max}$ ), moderate (65%  $\text{VO}_2\text{max}$ ), and high (85%  $\text{VO}_2\text{max}$ ) intensity is depicted. The main fuel source during high-intensity exercise ( $>70$ –75%  $\text{VO}_2\text{max}$ ) is carbohydrate as glycogen from the muscle. Generally, the oxidation of plasma FFA provides the majority of energy during low-intensity exercise with little or no net utilization of intramuscular triglycerides (IMTG) or lipoprotein derived TG (122–124).

**Figure 1** Endogenous substrate utilization (mol HEP per min) during exercise of various intensities. (From Ref. 122.)

During moderate-intensity exercise (40–65%  $\text{VO}_2\text{max}$ ) fat oxidation, from an absolute point of view, reaches maximal rates, with the endogenous IMTG stores (including possibly lipoprotein-derived TG) contributing  $\sim 50\%$  of total energy expenditure (122,125).

The majority of the carbohydrates oxidized are derived from muscle glycogen stores. With increasing intensity, fat oxidation decreases substantially from a relative as well as a qualitative point of view. The precise mechanisms that explain the increase and the limitations in fat oxidation during exercise are not well understood. From rest to moderate-intensity exercise, the increase in fat oxidation is enabled by an increase in adipose tissue lipolytic rate, followed by an increase in plasma FFA availability. However, plasma FFA oxidation is limited by yet undetermined factors, which likely include FFA transport from the vascular space into the intramyocellular compartment (126). This has led to an increased interest in the contribution of IMTG as endogenous fat source during moderate-intensity exercise (122). An increase in exercise intensity will result in an increased oxidation of IMTG, enabled by an increase in intracellular FA availability and an increase in the activity of the enzymes involved in the transport of FA over the mitochondrial membrane (127,128). By contrast, protein oxidation during exercise is small (129).

## 2 Exercise Duration

With increased duration of exercise the intramuscular fuel sources will diminish while the contribution from the circulating fuels will increase (122,130–135). During the initial phase of exercise, carbohydrate is mainly supplied from intramuscular glycogen stores (136,137).

After ~30–40 min of exercise, the contribution of blood glucose increases (131) and remains relatively constant (122,136) until the later stages of prolonged exercise, when it declines (137). The blood glucose level is maintained through an increase in hepatic glucose production (131,137). Initially, this is mainly due to hepatic glycogenolysis, but with prolonged exercise, gluconeogenesis becomes more important (131,138–140). Optimal carbohydrate ingestion can completely suppress hepatic glucose production during exercise (141).

Also, IMTG appears to be utilized more during the initial phase of moderate exercise with an increasing contribution from circulating FFA as time progresses. Although the contribution of protein to fuel utilization during exercise is small, < 11% of total energy expended (142), this can increase with very prolonged exercise. Protein contributes to energy production directly via oxidation of branched chain amino acids (BCAA) and indirectly through the increased release of the gluconeogenic precursor alanine (129). Protein synthesis in muscle declines whereas proteolysis in other tissues can increase the circulating BCAA (129,143). This increases the amino acid pool available for oxidation. As gluconeogenesis becomes more important during exercise, alanine release also rises (144).

## B Characteristics of the Exercising Individual

Both the amount of energy expended during exercise and the source of fuel for the added energy expenditure are influenced by several characteristics of the exercising individual.

### 1 Training Status

Christensen and Hansen (145), in their classic studies, observed that endurance training leads to an increased capacity to utilize fat as a fuel source. This training-induced change in substrate utilization has been confirmed in numerous studies (125,146–148). The contribution of fat as a fuel source during exercise has been shown to be increased in an endurance-trained state, compared at the same absolute and the same relative (and therefore higher absolute) workload (139). Saris (120) calculated that during 30 min of exercise at 60%  $\text{VO}_2\text{max}$ , trained individuals would oxidize an extra 10 g of fat as compared to sedentary individuals. The main metabolic adaptations to endurance training that are responsible for the increased fat oxidative capacity include an increase in both the size and number of mitochondria and a concomitant enhanced activity of enzymes involved in the uptake and oxidation of fatty

acids, as well as enzymes involved in the TCA cycle and respiratory chain (127,149).

Increased proportions of oxidative type I fibers and decreased proportions of type IIb fibers (except in sprint athletes) result following exercise training, so skeletal muscle is more adapted to fat oxidation. Similarly, the activity of important enzymes in fat and carbohydrate oxidation is modified. Exercise training leads to an increased ability to remove FFA from the circulation (142), which will also facilitate an increase in FFA oxidation. This is most probably mediated by an increase in membrane-associated fatty acid-binding proteins (FABP) (150). In addition, some of the increased fat oxidation in trained individuals may be due to a greater reliance on IMTG as an exercise fuel source. This is suggested by a greater decline in IMTG post-exercise following a period of training (147) and an inability of the increased FFA uptake to account for all the increase in total fat oxidation observed during exercise (125,151). However postexercise fat intake repletes IMTG but not faster in trained than in sedentary individuals (152). This increased lipid oxidation essentially spares both muscle glycogen and blood glucose (125,147,151). Other training adaptations relating to carbohydrate metabolism include a greater capacity for muscle glycogen storage (153) and an increased lactate clearance, which provides more gluconeogenic substrate (154).

### 2 Gender

There is abundant evidence that the proportion of energy derived from fat during exercise is higher in women than in men (155,156). Most studies have shown a greater fat oxidation (adjusted for energy expenditure) during submaximal exercise in women than in men (157–159). Also, a lower skeletal muscle glucose uptake (159) and attenuated muscle glycogen utilization (160) have been reported during exercise in women.

One factor of importance may be the differences in FFA availability. It has been shown that lipolysis as indicated by the rate of appearance of glycerol is higher in women than in men during exercise (159). Others, however, did not find a difference in rate of appearance of FFA (157,161). Also, a higher level of IMTG was found in women compared to men matched for lifestyle habits and insulin sensitivity (162).

This could indicate that higher IMTG oxidation may contribute to the increased fat oxidation of women during exercise as suggested before (160). Also, higher expression of FABP mRNA was found in women compared to men (163). From all these indications

it becomes clear that women have a higher capacity for FA transport and storage in the muscle, leading to a higher fat oxidation rate at the same relative exercise intensity.

The stage of menstrual cycle in females may also affect the pattern of fuel oxidation. Although few adequately controlled studies have been performed in this area, there is a suggestion of increased lipid oxidation during exercise performed in the luteal versus follicular phase of the menstrual cycle (164,165). Further work is warranted to more accurately elucidate potential gender-related aspects of exercising fuel metabolism. This will also give more information about the regulatory factors influencing fat versus carbohydrate oxidation during exercise.

### 3 Age

It has been suggested that the ability to oxidize fat during exercise declines with age (166). If true, this could be due to changes in the morphology and metabolism of skeletal muscles, and/or to availability of lipid substrate during exercise.

### 4 Body Composition

In the past years new data suggest that increases in body fatness promote insulin resistance and NIDDM. The progression in insulin resistance is accompanied by increased circulating concentrations of FFA. On the one hand, these increased FFA concentrations may result from the expended adipose tissue stores in obesity and NIDDM by a mass action effect or by a diminished ability of insulin to inhibit lipolysis. Both the beta-adrenergic stimulation and exercise stimulation of lipolysis and fat oxidation are impaired in the obese and NIDDM subjects (167–169). On the other hand, the uptake of FFA is impaired in skeletal muscle of the obese and obese NIDDM subjects during exercise (167,169). An increased IMTG has been hypothesized to be a key feature in the development of skeletal muscle insulin resistance (170). This is most probably mediated by a lower ability to increase muscle lipolysis during exercise as was shown in NIDDM (171) and obese (172,173) subjects. In Figure 2, relative fat source utilization during moderate intensity exercise is depicted from selected groups of subjects using the same measurement protocol (174,169,175).

Sedentary untrained and trained as well as highly trained healthy subjects are compared with obese and obese NIDDM subjects. Although subjects are not matched for age and body fatness, the figure illustrates clearly the low contribution of other fat sources

**Figure 2** Relative endogenous carbohydrate and fat source utilization during moderate-intensity exercise in lean sedentary subjects before and after a 3-month training period (from Ref. 220), highly trained athletes (from Ref. 174), and obese and obese NIDDM subjects (from Ref. 169).

(IMTG and lipoprotein-derived TG) in the substrate utilization during moderate intensity exercise in the obese state. Although not measured, it is assumed based on the available literature that in the obese and NIDDM groups the IMTG is higher than in the lean sedentary and trained subjects. In highly trained athletes, high levels of IMTG are found. Despite the similar high levels of IMTG in the obese and obese NIDDM groups, trained athletes show a very large capacity to use the other fat sources, in particular the IMTG stores. This topic clearly needs further attention in future studies because it can give us more insight in the detrimental role of fat stores in obesity and NIDDM.

## VII ROLE OF PHYSICAL ACTIVITY IN THE ETIOLOGY OF OBESITY

The most recent report from the National Health and Examination Survey (176) shows that the prevalence of obesity in the United States continues to increase, and was at 31%. While this is further evidence that factors in the U.S. environment are contributing to the population weight gain, it is not clear whether these environmental factors are influencing energy intake, energy expenditure, or both. Dramatic changes in the food supply and in the need for physical activity in daily life have both occurred over the past century, and each could be

contributing to weight gain. Unfortunately, population-based records of food intake are not very accurate, and physical-activity data (especially lifestyle or nonleisure physical activity) have not been systematically recorded. It is interesting to note that national household surveys of several different countries show a decrease in energy intake over time. For example, in Great Britain, energy intake decreased by more than 500 kcal from 1970 to 1990 (177). During the same time, however, body mass index and average body weight increased by 1.0 BMI unit and 2.5 kg, respectively. These figures would imply that energy expenditure must have declined by even >500 kcal. The problem is, we do not have any data to show whether this might be the case other than anecdotal information on the number of automobiles and occupational mechanization. While definitive data may be lacking, in this section we will examine the available data suggesting a causal link between physical activity and obesity.

#### **A Relationship Between Physical Activity and Body Fatness**

Epidemiological studies have consistently shown a negative relationship between measures of physical activity (usually self-reports) and indices of obesity (usually body mass index) (178). This relationship is present in most datasets obtained from the general U.S. population (179,180). The relationship appears to be similar in men and women, and across all ages (181–184). Further, there is evidence for a similar relationship in African-Americans (185), Hispanics (186), and Native Americans (187). This inverse relationship between BMI and physical activity has been seen using both self-reports of amount of physical activity (180) and actual energy expended in physical activity assessed from doubly labeled water measures (188,189).

Given that there is a negative relationship between obesity and physical activity and given that obesity is increasing dramatically in the population, can we attribute some of this weight gain to reduced energy expenditure due to declines in energy expended in physical activity, and can we reduce this weight gain with efforts to promote physical activity?

#### **B Do Low Levels of Physical Activity Increase the Risk of Obesity?**

Despite the lack of randomized, controlled studies, there is substantial evidence that low levels of physical activity may be contributing to the increased prevalence of obesity in the United States population. In several

cohort studies where indices of obesity over time were assessed without intervention, associations between low levels of physical activity and indices of obesity were found (190–193). In these studies, baseline measures of physical activity were inversely related to BMI. In some, low levels of physical activity predicted high weight gain over the follow-up period (191–193), and decreases in physical activity over time were associated with high weight gain (191–193).

Reduced levels of physical activity with age in the general population may play a role in the development of obesity. Reductions in physical activity could alter fiber type composition toward a greater proportion of glycolytic type IIb fibers that have a reduced capacity for fat utilization and may predispose to fat accumulation. This could lead to a vicious cycle of reduced physical activity resulting in further increased type IIb fiber proportions and decline in fat oxidation, thus promoting obesity. If a low level of physical activity contributes to weight gain, can we document a decline in overall physical activity that coincides with the increased prevalence of obesity seen over the past two decades?

#### **C Secular Trends in Physical Activity**

For our purposes, we can divide total physical activity into that activity performed intentionally during leisure time (leisure time physical activity; LTPA) or activity performed in daily living (lifestyle physical activity; LSPA). Are there clear secular trends in LTPA and LSPA?

While there are ample data indicating that the vast majority of Americans get little or no LTPA, there is little evidence that this has changed dramatically over the past two decades (194–196). It is not possible from existing data to conclude that substantial decreases in LTPA have occurred simultaneously with the onset of the obesity epidemic. It is more likely that declines in LSPA have contributed to the increased prevalence of obesity, but unfortunately it is difficult to quantify this contribution. While most obesity experts accept that technological advances have reduced the amount of LSPA required, this decline has not been documented to the extent to allow quantification of the changes. In fact, it is only in recent years that attempts have begun to measure LSPA. All indications are that work-related physical activity has declined. The only prospective data available come from Finland, where a 225 kJ/d decline in work-related physical activity has occurred over 10 years (197). Similarly, there is reason to believe that other forms of energy expended in activities of daily

living have declined rapidly over the past two or three decades. One can, for example, estimate the energy savings due to proliferation of televisions and computers, remote control devices, microwave ovens and increased use of prepared foods. While each may reduce physical activity only slightly, together these energy savings accumulate and can have a significant impact on total energy expenditure. Declines in energy expended for transportation have also likely occurred in recent years. This can best be illustrated with data from the National Personal Transportation Survey (198). In the United States between 1990 and 1995, the number of annual walking trips had declined 12.4%, while the number of daily car trips had increased nearly an identical amount (12.3%).

The total amount of energy expended in physical activity may also be declining owing to an increase in attractive sedentary activities such as television watching, video games, and computer interactions. Again, we do not have good measures of sedentary activity that would allow us to examine how time spent in these activities has changed over the past few years. It is likely, however, that these highly attractive sedentary activities are successfully competing with LTPA for our leisure time.

#### **D Does Increasing Physical Activity Prevent Weight Gain?**

If declines in physical activity have contributed to weight gain, it may be possible to prevent or slow weight gain by increasing physical activity. There have been surprisingly few prospective intervention studies to examine this question, but several observational studies are relevant. DiPietro et al. (199) measured a group of adults coming to the Cooper Clinic at baseline and 7.5 years later. They found that higher levels of aerobic fitness were associated with lower weight gain in this population. However, they reported that, over time, increases in fitness were necessary for subjects to remain weight stable. Williams (200) found that even among a highly active group of runners, increasing amounts of physical activity with increasing age were needed to prevent weight gain. Ching et al. (201) found that the combination of high levels of physical activity and a low amount of time spent watching television/VCR was associated with a lower BMI at baseline and with lower weight gain over time. Sherwood et al. (202) found that a high level of physical activity was one of the factors that were protective against weight gain in the Pound study. These authors point out, however,

that a number of factors seem to interact to influence weight gain over time.

In children, prospective intervention studies do suggest that increasing physical activity can prevent weight gain. Epstein et al. (203) and Robinson (204) have reported success in increasing physical activity through reduction in sedentary activities (e.g., TV, video games).

#### **E How Much Physical Activity Is Required to Prevent Weight Gain?**

There is no consensus about how much physical activity is required to prevent weight gain. The Surgeon-General recommends accumulation of at least 30 min of moderate-intensity physical activity on most days and on at least 3 days a week (205). At the time of development of these recommendations, there were few or no data relating amount of physical activity to weight gain, so the recommendations were made using data about physical-activity level and risk of cardiovascular disease and mortality rates. The question is whether the data now available are helpful in defining physical activity recommendations to prevent weight gain.

It may be helpful to consider prevention of weight gain separately from prevention of weight regain. We have more data about the amount of physical activity required to prevent weight regain in reduced-obese subjects than we have about the amount of physical activity required to prevent weight gain over time in the never-obese. It is not clear if more physical activity is required to prevent weight regain than to prevent weight gain, but this should be considered as a possibility.

#### **F Prevention of Weight Regain**

There is surprising consensus about the amount of physical activity that seems to help maintain weight loss and prevent weight regain. This amount may be 60–90 min of moderate-intensity physical activity each day—substantially more physical activity than recommended for health by the Surgeon-General. Schoeller et al. (206) found that a PAL of 1.75 ( $1.75 \times$  basal metabolic rate) was protective against weight regain in a group of obese-reduced subjects. They recommended 80 min/day of moderate-intensity physical activity to prevent weight regain. Studies of the National Weight Control Registry show that subjects maintaining an average weight loss of 30 kg for an average of 5.5 years reported expending from 2545 kcal/week (women) to 3293 kcal/week (men) in physical activity (207). This would be equivalent to 60–90 min of moderate-intensity physical activity.

Jakicic et al. (208) found that reduced-obese subjects who engaged in at least 200 min/week of physical activity were less likely to regain weight than those who engaged in less physical activity. Finally, Weinsier et al. (209) studied women who maintained or gained weight over time. They found that weight maintainers were more physically active than weight gainers. They estimated that it may take as much as 80 min/day to maintain body weight (depending on diet). It should be noted, however, that the weight maintainers included some women who were previously obese and some who had never been obese.

### G Prevention of Weight Gain

There are far fewer data available about how much physical activity is required to prevent the weight gain over time seen in the general population. This amount of weight gain may be on the order of 0.5–1.0 kg/year (55). Theoretically, an adult could gain 1 kg of body fat over 1 year with an energy imbalance of <50 kcal/d. This might suggest that the amount of physical activity required to prevent this weight gain could be relatively small. However, we have no prospective studies that have tested this assumption.

### H What Characteristics of Physical Activity Are Important in Preventing Weight Gain?

At present there are insufficient data to recommend specific types of physical activity for prevention of weight gain. Some have suggested that more vigorous physical activity may be better, independent of total energy expended (210); others suggest that resistance training may be useful (211). It is interesting to note that subjects in the National Weight Control Registry report engaging in weightlifting to a greater extent than is seen in the general population. On the other hand, West-erterp (212) noted that the cumulative impact of low-intensity activities over greater duration is of greater energetic impact than short bursts of high-intensity physical activities in free-living individuals. Thus, not only are recommendations for exercise germane but also those to reverse sedentariness.

### I How to Increase Physical Activity?

While definitive randomized controlled studies showing that increasing physical activity can prevent weight gain are lacking, substantial indirect evidence suggests that increasing physical activity is likely to be one of

our most effective strategies for reducing the weight gain seen in the general population. The evidence is strong enough that we should expand the efforts toward understanding how to get the population more physically active.

Attempts to increase physical activity by increasing LTPA have not met with overwhelming success, since LTPA has not increased over the past decade (194–196), but efforts to increase LSPA may be more promising (213,214). Increasing walking could be effective in increasing physical activity sufficiently to prevent weight gain (215). A limitation in promoting LSPA has been the difficulty in measuring it, but technological advances have brought pedometers and accelerometers that allow the individual some feedback about amount of LSPA performed (216–218). These devices may prove to be very useful in population efforts to increase physical activity. It will also be necessary to consider policy strategies to promote physical activity, as was reviewed elsewhere (219).

## Endocrine Determinants of Obesity

**Jonathan H. Pinkney**

**Peter G. Kopelman**

Barts and the London Queen Mary's School of Medicine and Dentistry, University of London, London, England

### I INTRODUCTION

Obesity is a fundamental disorder of energy balance in which excessive energy stores accumulate in the form of fat in response to sustained high energy intake and/or low expenditure. While genetic factors influence obesity through endocrine mechanisms, the majority of endocrine changes observed in obese subjects are consequences of obesity. The endocrine mechanisms giving rise to disturbances of fat distribution, and by which obesity gives rise to its principal complications—diabetes, cardiovascular disease, and female reproductive dysfunction—are becoming clear. In this chapter we consider the unusual primary endocrine causes of obesity, including recently described genetic syndromes, and then focus on the more common alterations in endocrine function that are characteristic of obesity—disturbances in insulin secretion and action, adrenocortical function, sex steroid secretion, the growth hormone–insulinlike growth factor and pituitary–thyroid axes. The evidence that these changes play a role in either the determination of corpulence or the perpetuation of the obese state is considered.

### II PRIMARY ENDOCRINE DISEASE AS A CAUSE OF OBESITY

Diseases in which primary endocrine disturbances are the cause of obesity are unusual in clinical practice. This group of disorders (Table 1) includes structural lesions of the hypothalamus, of which craniopharyngioma, or its treatment with surgery or radiotherapy, is the commonest. The mechanisms responsible for weight gain in this situation include hyperphagia, reduced resting metabolic rate, and autonomic imbalance leading to hyperinsulinemia (1). Treatment, which reduces insulin secretion, promotes weight loss in a subset of such patients (2). Patients with growth hormone (GH) deficiency secondary to pituitary/hypothalamic disease also have increased body fat and reduced muscle mass, and this is corrected by GH replacement (3–7). Genetic defects affecting the function of this brain region include Prader-Willi syndrome, until recently the commonest known monogenic form of obesity. Mutations in leptin, leptin receptor, pro-opiomelanocortin (POMC), and melanocortin-4 receptor (MC4R) have now been described in obese humans (8–11), but these are rare

**Table 1** Primary Endocrine Causes of Obesity in Humans

|  |
|--|
| Structural damage to hypothalamus                          |
| Craniopharyngioma  |
| Pituitary macroadenoma with suprasellar extension          |
| Other space-occupying lesions                              |
| Trauma   |
| Infiltration   |
| Inflammation   |
| Surgery and radiotherapy                                   |
| Other contributing factors                                 |
| GH deficiency  |
| Hypogonadism   |
| Panhypopituitarism   |
| Genetic syndromes of obesity with hypothalamic dysfunction |
| Prader-Willi syndrome                                      |
| Leptin deficiency  |
| Leptin receptor deficiency                                 |
| POMC mutation  |
| Melanocortin-4 receptor mutation                           |

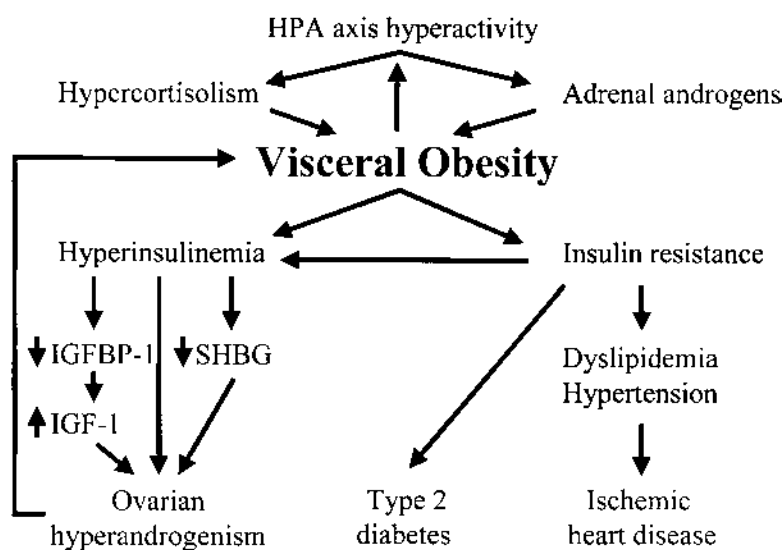

in clinical practice. Hyperphagia is the main mechanism leading to obesity. MC4R mutations, however, appear to be more common, present in possibly 4% of morbidly obese patients (12). As genome scans identify other loci linked to human obesity new genes await discovery. However, overt endocrine defects of primary significance are seldom observed in the obesity clinic, confirming that most of the observed endocrine changes are adaptations to obesity.

### III INSULIN SECRETION AND ACTION IN OBESITY

A major consequence of obesity is impaired insulin action, and this leads to increased insulin secretion from islet  $\beta$ -cells. This abnormality is fundamental to understanding the metabolic complications of obesity (Fig. 1). Insulin resistance and hyperinsulinemia are central to the pathogenesis of ischemic heart disease (13), and, in individuals whose  $\beta$ -cells are unable to compensate for insulin resistance, glucose tolerance is progressively impaired and type 2 diabetes supervenes (14).

Although obesity is characterized by elevated fasting insulin and exaggerated insulin response to oral glucose (15), it is intra-abdominal fat deposition—central obesity—that is particularly associated with a decline in insulin sensitivity (16). Hepatic insulin extraction is reduced in central obesity (17), further increasing plasma insulin levels. While increased body weight moderately reduces hepatic and peripheral insulin sensitivity, central obesity causes far greater impairments. With the advent of computed tomography and magnetic resonance imaging, it has been possible to confirm that visceral, rather than overall, adipose tissue mass is primarily related to the decline in insulin sensitivity and accompanying defects (18).

Several mechanisms account for the effects of obesity on insulin action. Plasma fatty acid (FA) levels are elevated in obese subjects despite normal glucose homeostasis (19). Fatty acids impair insulin-stimulated

**Figure 1** Endocrine relationships among visceral obesity, insulin resistance, and steroid metabolism.

glucose uptake and oxidation in muscle (20) and insulin-mediated suppression of hepatic glucose output (21). It has been suggested that FA released by visceral fat play a key role in the impairment of liver and muscle insulin sensitivity (22). Recently, it has been suggested also that FA accumulation in muscle may be a key event in the impairment of insulin sensitivity (23).

Impaired glucose transport and insulin signaling have attracted attention as possible explanations for insulin resistance. In premenopausal women, insulin-stimulated activity of the enzyme glycogen synthase in quadriceps muscle declined with increasing obesity and insulin resistance during a somatostatin-insulin-dextrose infusion (24). An inverse relationship was observed between insulin receptor numbers and a measure of upper-body obesity, waist-to-hip ratio (WHR). Obesity was also associated with depletion of adipocyte glucose transporters (GLUT4) (25). Severe insulin resistance in type 2 diabetic patients was associated with a still greater fall in GLUT4 mRNA compared to simple obesity that involved both plasma membrane and cytosolic compartments. In both patient groups, suppression of GLUT4 mRNA expression entirely accounted for impaired insulin responsiveness in adipose tissue. In contrast, no differences were seen in skeletal muscle GLUT4 content or mRNA from control subjects (26). These studies support the concept of a primary defect in GLUT4 in adipocytes but not in muscle.

More recently, it has been shown in animal models that knockout of GLUT4 in adipose tissue leads to insulin resistance in liver and muscle (27). The mechanism responsible for this remains to be determined but FA are a leading candidate. Declining muscle insulin sensitivity may also result from decreased functional activity of GLUT4 or impairment of insulin-stimulated translocation of intracellular GLUT4 to the cell surface. It has been demonstrated that chronic exposure to high concentrations of glucose and insulin reduces insulin-stimulated glucose transporter translocation (28). Thus hyperglycemia and/or hyperinsulinemia may contribute to insulin resistance.

Many other hormones and mediators are released by adipose tissue (29), some affecting insulin secretion and/or action. Leptin was found by some (30,31), but not all, investigators to inhibit insulin signaling. However, leptin also inhibits insulin secretion (32), and this may impair glucose tolerance.  $\text{TNF}\alpha$  is also expressed in adipocytes and may cause insulin resistance in obesity (33). A comprehensive discussion of other factors is beyond the scope of this chapter. These include prostanoids, angiotensinogen, IGF-1, IL-6, adiponectin, complement components and related molecules, and

resistin. It is clear that there are many potential mechanisms through which an increased adipose tissue mass can influence insulin secretion and action.

#### IV ADRENOCORTICAL FUNCTION IN OBESITY

Obesity is associated with complex changes in the hypothalamic-pituitary (HPA) axis (Table 2). Obese subjects have normal plasma and urinary cortisol levels but accelerated cortisol production and degradation (34,35), and the daytime variation is reduced with diminished morning peaks (36–38). A moderate elevation of plasma ACTH levels is seen in obesity (39), with the ACTH response to insulin-induced hypoglycemia positively correlating with body weight (40). Furthermore, HPA axis activation after a meal is greater in women with central than peripheral obesity or normal weight (41). Hyperreactivity of the HPA axis in obese subjects to both neuropeptides and stress is also observed (42). Elevations in stress-related salivary cortisol profiles have been associated with central obesity in men (43), which supports the concept that stress may predispose to central obesity through HPA axis activation.

There are several additional lines of evidence that demonstrate the association of increased HPA activity and central obesity. Cortisol inhibits the antilipolytic effects of insulin in adipocytes, and this may be more pronounced in visceral adipose tissue (VAT), which contains increased numbers of glucocorticoid receptors (44). Increased cortisol clearance may result from a decrease in cortisol-binding globulin, as well as increased glucocorticoid receptor binding (45), especially in visceral adipocytes with a high density of glucocorticoid receptors (46). It has been suggested that increased expression of 11- $\beta$ -hydroxysteroid dehydrogenase in omental fat also may increase local cortisol production, thereby promoting central obesity (47).

**Table 2** Principal Abnormalities of the HPA Axis in Obesity

---

|   |
|---|
| Increased stress-induced ACTH secretion |
| Increased cortisol secretion            |
| Decreased cortisol-binding globulin     |
| Increased cortisol clearance            |
| Flat diurnal cortisol profile           |
| Reduced morning cortisol peak           |
| Impaired dexamethasone suppression      |
| Increased adrenal androgen production   |
| Normal 24-hr urinary cortisol levels    |

---

The obesity-related acceleration in adrenocortical function and cortisol clearance is associated with an increased adrenal androgen production and increased urinary 17-ketosteroid excretion. (48). Increased dehydroepiandrosterone (DHEA) turnover occurs in obese women (49), and androgen clearance correlates with WHR. In premenopausal women serum DHEA correlates positively with truncal but negatively with leg fat, whereas these effects are not seen in men (50,51). In women, a shift toward central fat deposition may be an androgenic effect of DHEA. In healthy postmenopausal women, androgen levels are inversely related to fasting plasma glucose levels, and predict central obesity 15 years later (52). A positive correlation is reported between body weight and changes in DHEA and DHEA/17-hydroxyprogesterone ratio after administration of ACTH (53). In vitro studies also suggest less inhibition of 17-hydroxylase compared to 17,20-desmolase by DHEA (54), favoring further androgen production. Thus, DHEA may contribute to abdominal fat cell accumulation with resulting insulin resistance and hyperinsulinemia. The latter depresses SHBG, resulting in an increase in free testosterone levels and further visceral fat accumulation.

In conclusion, dysregulation of the HPA axis in obesity—especially central obesity—results from two distinct alterations. The first is central and characterized by altered ACTH secretory dynamics and hyperresponsiveness of the HPA axis. The other is located in the periphery, including visceral adipose tissue, and is characterized by supranormal cortisol production and tissue response.

## V CUSHING'S SYNDROME AND OBESITY

There are many similarities between central obesity and Cushing's syndrome. Cushing's syndrome is characterized by insulin resistance, impaired glucose tolerance, hypertension, dyslipidemia, central obesity, and muscle weakness (55). In addition, decreased plasma SHBG and raised free testosterone levels are features of Cushing's syndrome. Furthermore, women with central obesity and women with Cushing's syndrome do not show the typical female increase in fat cell size and LPL activity in femoral versus abdominal adipocytes. Instead, LPL activity in enlarged abdominal fat cells is increased two to three times that of normal-weight women. It is likely that this results from a combined action of increased cortisol and insulin: human adipose tissue exposed in vitro to high concentrations of cortisol shows increased LPL activity in the presence of insulin (44).

These findings suggest cortisol has a preferential effect on abdominal fat because no clear difference from normal is found in femoral fat. This may reflect increased glucocorticoid receptors in abdominal fat (46). Diminished lipolysis in Cushing's syndrome results in a decreased capacity of abdominal fat cells to mobilize fat, leading to adipocyte enlargement. Thus, central obesity in Cushing's syndrome may result from increased LPL activity and reduced lipolysis.

Muscle changes in central obesity and Cushing's syndrome are also similar. Subjects with central obesity show a relative decrease in type I muscle fibers, as in Cushing's syndrome (55). In women with Cushing's syndrome, vastus lateralis muscle contains normal glycogen levels but very low glycogen synthase activity, the likely consequence of reduced insulin sensitivity (55). Fiber composition in such women (and in women with central obesity who were not cushingoid) is characterized by relative abundance of type IIb and scarcity of type I fibers compared to women with gynoid obesity. Moreover, a correlation is seen between the proportion of type I fibers and insulin sensitivity, and between type IIb and insulin resistance: type I fibers show higher insulin sensitivity and bind insulin more efficiently. Thus, the muscle fiber composition in Cushing's syndrome resembles that seen in central obesity.

## VI REGIONAL DISTRIBUTION OF ADIPOSE TISSUE

Fat topography can be defined at two levels: first, by individual differences in adipose tissue cell characteristics, and second, by the anatomical distribution of body fat (56,57). The factors controlling fat localization are not fully understood, but regional differences in lipolysis may play a role. Human adipose tissue is richly endowed with  $\beta_2$ -,  $\beta_3$ -, and  $\alpha_2$ -adrenoceptors; agonists at  $\beta_2/\beta_3$ -receptors enhance lipolysis whereas  $\alpha_2$ -agonists inhibit lipolysis. In both men and women, the lipolytic response to norepinephrine is more marked in abdominal than gluteal or femoral fat (56). Furthermore, analysis in men and women suggests that male fat distribution reflects predominance of  $\alpha_2$ - over  $\beta$ -adrenergic activity in abdominal fat (58). There is considerable evidence that LPL activity influences regional fat distribution. There are significant gender and regional differences in LPL activity that parallel variations in adiposity. Premenopausal women have higher LPL activities in gluteal and femoral regions than men, but this difference disappears after the menopause (59). In addition, women have quantitatively more LPL in

gluteal and femoral fat, which contains larger cells, than they do in abdominal adipocytes. These differences in fat distribution between men and women may be explained by the tendency for premenopausal women to deposit fat preferentially in subcutaneous depots. A regional difference is seen in the response of adipose tissue to catecholamine-induced lipolysis, which is probably localized at the adrenoceptor level: stimulation of protein kinase abolishes the lipolytic differences between site and gender (60). Insulin is permissive for LPL synthesis, and glucocorticoids enhance the activity of LPL when added with insulin *in vitro* (44). Sex steroids are strongly implicated in the regional distribution of body fat, and gender differences are seen also in LPL activity particularly during pregnancy and lactation (61). It is likely that regional variation in receptors for glucocorticoids and sex steroids plays an important role in determining regional fat distribution. Endocrine determinants of fat distribution are discussed at length elsewhere in this volume.

## VII SEX STEROID SECRETION IN OBESITY

Excess fat accumulation in women is associated with ovulatory dysfunction, hyperandrogenism, and the development of hormone-sensitive carcinomas (62). Both overall adiposity and fat distribution correlate with these changes (63,64). Menarche frequently occurs at a younger age in obese girls and menstrual abnormalities are common in adulthood (65). Weight loss has a salutary effect on ovulatory function with the return of menses in previously amenorrheic obese women. Obese women exhibit distinct changes in sex steroid levels (64). Androstenedione and testosterone plasma concentrations are often elevated, sex hormone-binding globulin (SHBG) levels reduced, and the plasma ratio of estrone to estradiol increased. This is similar to the patterns found in women with polycystic ovary syndrome. Evans and colleagues (63) showed that body weight and WHR correlate inversely with SHBG levels and directly with free testosterone. Others describe a higher production rate from the adrenal cortex and ovaries and increased clearance of testosterone and dihydrotestosterone (64). The clearance of testosterone increases as SHBG decreases, the consequence of an increased fraction of unbound testosterone available for hepatic extraction and clearance (65). Fat is able to sequester steroids, including androgens, because of their lipid solubility, and most sex steroids are preferentially concentrated within adipocytes rather than plasma (66). As a result,

the steroid pool is greater in obese than in lean subjects; the fat volume in obese subjects is much larger than the intravascular space, and tissue steroid levels are 2–13 times higher than in plasma. Fat serves not only as a reservoir but also as a site for steroid metabolism. Androgens are irreversibly aromatized to estrogens or reversibly converted to other androgens (67).

There are two possible explanations for the obesity-related increase in androgen production rate. The first is hypothalamic-pituitary-gonadal and adrenal compensation for increased clearance. Alternatively, the increase in ovarian and adrenal production is stimulated by factors such as insulin and, with falling SHBG production, increased bioactivity and clearance of free steroid (68). Increased androgen levels favor central fat deposition with an additional increase in steroid clearance through adipose tissue sequestration and metabolism. Unlike most hormone receptors, the number of androgen receptors in fat cells increases with exposure to testosterone. Interestingly, hypogonadism in men is associated with a significant decrease in the lipolytic response to catecholamines while treatment with testosterone normalizes this response and increases triglyceride turnover. The lipolytic effect of testosterone is mediated by an increase in  $\beta$ -adrenoceptor numbers and the activity of adenylate cyclase, protein kinase A, and hormone-sensitive lipase. The density of abdominal subcutaneous adipose tissue  $\alpha$ -adrenoceptors is higher in men than in women. Thus, although the main effect of androgens is lipolytic, these hormones may also increase the number of antilipolytic adrenoceptors. Long-term treatment with testosterone of hypogonadal men leads to a marked decrease in both LPL activity and FA uptake in abdominal but not femoral subcutaneous fat. Moreover, the inhibition of lipid uptake after testosterone administration is more apparent in visceral than in abdominal subcutaneous adipose tissue. Such results are in line with studies that show androgen receptors have a higher density in visceral fat than in subcutaneous fat cells (69).

Obesity in men is characterized by reductions in total and free testosterone, and SHBG concentrations. Such men with lower free testosterone have lower lipolytic responses to catecholamines and higher LPL activity in adipose tissue. These metabolic adaptations may contribute to the lower triglyceride turnover and body fat accumulation in these subjects (70). In addition, there is a strong negative correlation between leptin and free testosterone that is independent of plasma insulin concentration. This may be the explanation for the lower serum leptin levels in men compared to women (71).

## VIII ESTROGEN METABOLISM IN OBESITY

Excess body fat leads to changes in the hypothalamic-pituitary-ovarian axis and ovarian function (72). The production of estrogen and its precursors, including androstenedione and testosterone, decreases with age and after the menopause. In premenopausal women, mean 24-hr plasma estrone and estradiol levels do not differ in obese and lean women (73). However, obese women have lower SHBG levels and increased free estrogen. In postmenopausal obese women, serum estrone and estradiol correlate with fat mass (74). SHBG levels are also lower in older women, further elevating free estradiol levels. Aromatization of androstenedione to estrone occurs in adipose tissue of premenopausal and postmenopausal women and is closely related to body weight (75). Aromatization increases with age and is two to four times higher in postmenopausal women (76). Androstenedione is the major substrate for estrogen formation; although only a small amount of testosterone is aromatized, this may be of greater significance. Longcope and colleagues (77) have reported associations between body weight and the conversion of testosterone to estradiol. The interconversion of estrone to estradiol is also greater in omental than subcutaneous fat (78,79). Furthermore, adipose tissue 17-hydroxysteroid dehydrogenase activity, measured by the conversion of estrone to estradiol, is higher in premenopausal than postmenopausal women, and women have higher activity than men (78). Estrogens should not be considered as passive byproducts of obesity because they positively promote preadipocyte proliferation, preservation, and further expansion of adipose tissue (79).

## IX SEX HORMONE-BINDING GLOBULIN IN OBESITY

Sex hormone-binding globulin (SHBG), produced by the liver, binds to sex steroids in high affinity but low capacity (80). Levels of SHBG are inversely related to fat mass and WHR (63), so obesity results in increased free steroid levels and clearance. Aromatization rates correlate with free rather than total androgen. The lower affinity of SHBG for estradiol relative to testosterone also results in an estrogen amplification effect on sensitive tissues (particularly the liver) with decreasing SHBG levels (80). Central obesity in women is characterized by higher total testosterone, with increased production rates, increased estradiol, and reduced SHBG compared to lower body obesity (81).

Obesity probably influences SHBG production by several mechanisms. Obesity-related hyperandrogenism may itself reduce SHBG levels, increasing clearance of testosterone and estradiol (72). However, insulin inhibits SHBG synthesis (82), and hyperinsulinemia is probably the main mechanism leading to the fall in SHBG production in central obesity. Hyperinsulinemia, in conjunction with increased free IGF-1, further increases ovarian androgen secretion, thereby contributing to a vicious circle of events (68,83).

## X POLYCYSTIC OVARY SYNDROME AND OBESITY

The polycystic ovary syndrome (PCOS) (84) is the most common endocrine disorder of reproduction. Moderate degrees of excess bodyweight are frequently observed in the syndrome, fueling speculation that obesity is a causal factor. The multiple endocrine and metabolic defects associated with PCOS are summarized in Table 3.

The ovaries in PCOS show thickened cortices and increased numbers of atretic follicles. The androgen-producing stroma are usually hyperplastic. There is hyperplasia of thecal cells, and immature granulosa cells are unable to convert androgens to estrogens. Many of these features are seen in obese women with normal menstrual function, but in this circumstance the ovary is not enlarged (85). Similar morphology is seen in women with Cushing's disease and congenital adrenal hyperplasia, syndromes also associated with hyperandrogenism (86). What are the common features of PCOS and obesity, and is it possible to distinguish PCOS from obesity?

**Table 3** Principal Metabolic Abnormalities Associated with Obesity and the PCOS

---

|  |
|--|
| Insulin resistance                         |
| Hyperinsulinemia                           |
| Impaired glucose tolerance                 |
| Type 2 diabetes                            |
| Dyslipidemia                               |
| Increased adrenal androgen secretion       |
| Increased ovarian testosterone secretion   |
| Increased aromatization of androstenedione |
| Increased estrone/estradiol ratio          |
| Decreased SHBG                             |
| Decreased IGFBP-1                          |
| Increased free steroid concentrations      |

---

In contrast to obesity, the ovaries in PCOS are the major source of androgens, with LH-dependent production (86). PCOS is characterized by increased plasma androstenedione and testosterone and a reversed estradiol:estrone ratio. SHBG is also reduced in PCOS, as in obesity (63,87). Testosterone is formed in peripheral tissues by conversion from androstenedione, DHEA, and DHEAS, while estrone is both secreted by the ovaries and derived from extragonadal aromatization. In both PCOS and obesity, aromatization rates of androstenedione to estrone by adipose tissue correlate with body weight (88). In contrast to obesity, however, PCOS is marked by increased LH secretion, reflecting increased pituitary sensitivity to gonadotropin-releasing hormone (GnRH).

The etiology of PCOS is controversial. Much evidence supports a key role for insulin resistance, and this may explain the association of PCOS with obesity. Insulin increases free testosterone levels in PCOS by increasing production of testosterone and suppressing that of SHBG (89). Women with PCOS are insulin resistant and hyperinsulinemic, and often develop impaired glucose tolerance and type 2 diabetes (90). Although the degree of hyperinsulinemia is proportional to body weight, lean women with PCOS are also insulin resistant. In PCOS, as in obesity, increasing central obesity is associated with insulin resistance and reduced hepatic insulin extraction (68). Obese women with PCOS are significantly more hyperinsulinemic than nonobese women with PCOS (91). However, suppression of gonadal steroidogenesis with a long-acting GnRH analog does not affect plasma insulin levels or insulin sensitivity (92), which argues against steroids as the cause of insulin resistance. Hyperinsulinemia may drive ovarian steroidogenesis to produce PCOS (68). Nestler and colleagues (93) observed a fall in plasma insulin and testosterone levels in obese women with PCOS given diazoxide, with no effect on gonadotropin release. Subsequent studies with the insulin-sensitizing agents metformin and thiazolidinediones (94–96) confirm the findings with diazoxide. Ovarian P450c17 $\alpha$ -hydroxylase activity declines markedly in obese and lean women with PCOS after the reduction of serum insulin with metformin (97).

An additional mechanism by which insulin influences androgen secretion involves IGFBP-1. Lean women with PCOS show a positive correlation between plasma insulin and IGF-1 concentrations and a negative one with IGFBP-1, a pattern identical to that in obesity (98). Since IGFBP-1 acts as an inhibitor of IGF-1 action, its suppression by insulin favors increased androgen production by increasing ovarian levels of free IGF-1. IGF-

1 is a potent amplifier of LH-induced androgen synthesis (99).

An alternative theory for the etiology of PCOS is the gonadotropin hypothesis, which postulates a primary role for increased LH secretion relative to FSH. Against a primary role for the hypothalamus in PCOS, however, is the fact that increased LH secretion is not a usual finding in most obese women of reproductive age, and this argues against increased gonadotropin secretion as the initial event in the obesity-PCOS relationship. Finally, the finding that weight loss improves menstrual function in obese women with PCOS (100) supports the contention that obesity is a cause of the ovarian disturbance.

## XI THE GROWTH HORMONE/ INSULINLIKE GROWTH FACTOR AXIS IN OBESITY

The growth hormone (GH)/insulinlike growth factor (IGF) axis is an important regulator of body composition throughout life. Multiple GH-IGF axis defects are present in obese individuals (Table 4), although these are usually maladaptive consequences, rather than primary etiological factors. However, GH hyposecretion is physiologically relevant to increasing body fatness. Subcutaneous fat is markedly increased in GH-deficient subjects (101), and abdominal rather than peripheral adiposity is closely associated with GH hyposecretion (102). In one study of GH-deficient subjects, visceral fat was decreased by 30% after 6 months' treatment with GH (103). GH deficiency is associated with impairments of lipolysis in fat and protein synthesis in muscle (104)—an unfavorable combination in the context of obesity. Several mechanisms contribute to reduced GH levels in obesity including inhibition of secretion by nutrient and neuroendocrine signals, increased binding, and clearance. GH secretion is reduced in response to both pharmacological and physiological stimuli (105). The reduction in GH secre-

**Table 4** Principal Abnormalities of the GH-IGF Axis in Obesity

| Increased GHBP secretion    |
| Decreased IGFBP-1           |
| Decreased IGFBP-3           |
| Low/normal total IGF-1      |
| Increased free IGF-1        |
| Decreased ghrelin secretion |

---

tion is due mainly to a reduction in pulse amplitude rather than frequency (106). The clearance of both exogenous GH and endogenous GH is increased in obesity (107,108), and the consequences of reduced GH secretion are further amplified by increased levels of GH-binding protein (GHBP) (109), particularly in central obesity (110).

Circulating FA levels are increased in obesity, and contribute to the downregulation of GH secretion. Thus, an intravenous lipid infusion impairs the GH response to GHRH in humans (111). A direct inhibitory effect of FA on pituitary GH secretion explains this phenomenon (112). The usual inhibitory effect of glucose on GH secretion is blunted in obesity, suggesting a disturbance of hypothalamic glucose sensing (113). Chronic carbohydrate overfeeding impairs GH responses without any increase in body weight (114). It is currently unclear whether this results from direct nutrient effects or neuroendocrine mechanisms. Insulin suppresses GH secretion *in vitro* (115), so hyperinsulinemia may contribute to GH hyposecretion in obesity. Other factors involved in the downregulation of GH secretion are IGF-1 and its binding proteins. IGF-binding protein 1 and 3 (IGFBP-1, IGFBP-3) are reduced in obesity; the decreased serum IGFBP-1 levels are inversely related to fasting insulin and WHR (116,117). Insulin stimulates synthesis of IGF-1 and suppresses that of IGFBP-1. The hyperinsulinemia of obesity, in conjunction with increased IGF-1 output from an expanded adipose tissue mass, may explain the elevated levels of free IGF-1 in obesity (118). Free IGF-1 exerts negative feedback on GH secretion in pituitary cells. Confirming this mechanism, the GH response to GHRH in obese humans is suppressed by exogenous IGF-1 (119). A final mechanism for GH hyposecretion is suggested by the recent finding of reduced plasma ghrelin levels in obesity (see below).

Evidence that GH hyposecretion contributes to the maintenance, and perhaps the pathophysiology, of the obese state, is provided by clinical trials of administering GH to obese subjects. In a 9-month study of rhGH in men with central obesity, total body and visceral fat declined by 9.2% and 18.1%, with improved glucose tolerance, lipid profile, and blood pressure (120). The mechanisms responsible for the beneficial effect on fat mass are probably multiple, including increased lipolysis (121), lean body mass, and resting metabolic rate (122). There is evidence that GH may augment plasma leptin levels in GH-deficient humans (123), which could promote negative energy balance, although GH has no effect on leptin in obese adults (122). Lastly, in preadipocytes, IGF-1 promotes and GH suppresses adipocyte differentiation (124,121), raising the interesting possi-

bility that the high IGF-1/low GH environment of obesity favors adipocyte differentiation. Finally, the observation that weight loss reverses the defects in GH and IGF-1 secretion (125) and reduces GHBP levels (126), confirms that these abnormalities are indeed secondary to obesity.

## XII GHRELIN AND OBESITY

A discussion of obesity and the GH-IGF axis would no longer be complete without mention of ghrelin. Ghrelin is a 28-amino acid GH secretagogue expressed in gut neuroendocrine cells—mainly in the gastric fundus, as well as the arcuate nucleus of the hypothalamus (127). Ghrelin is the endogenous ligand for the previously identified growth hormone secretagogue receptor (128). Whether administered to pituitary cells *in vitro*, ICV to animals, or by peripheral injection to animals and humans, ghrelin powerfully elicits GH secretion (129). Unexpectedly, both ICV and peripheral injection of ghrelin in animals and humans also elicited strong feeding responses, and weight gain was observed in animals. Gastric ghrelin expression and secretion increase with fasting and decline in the postprandial state. In the stomach, ghrelin has a prokinetic effect, whereas circulating ghrelin appears to stimulate feeding and induce weight gain and gastric acid secretion through central effects.

The effect on weight is probably mediated through central antagonism of leptin and other anorectic cytokines through signals delivered via vagal afferents, rather than a direct bloodborne effect on the hypothalamus (130). This action is mediated through increased expression of hypothalamic neuropeptide- Y (130) and Agouti-related protein (AGRP) (131). Reduced plasma ghrelin concentrations have been reported now in human obesity (132), and may result from the higher leptin or insulin levels in obese subjects. Both leptin and interleukin-1 $\beta$  reduce ghrelin expression in the stomach (130). Thus, circulating ghrelin controls hypothalamic sensitivity to anorectic signals while some of the same signals regulate peripheral ghrelin release.

Although the role of ghrelin in energy homeostasis remains to be fully clarified, on the basis of these data it has been proposed that both centrally released and peripheral circulating ghrelin of gastric origin are involved in the regulation of GH secretion and feeding, and therefore that circulating ghrelin explicitly impacts central control of feeding and GH secretion. Further research should clarify the extent to which these actions are distinct or intrinsically linked. Given this apparent dual role, however, it is possible that circulating ghrelin

couples activity of the GH-IGF axis to signals that induce negative energy balance such as leptin and cytokines. The defence of lean body mass in the fasting state—an important function of the GH-IGF axis—would be more efficient if concurrent anorectic and thermogenic signals could be shut down. However, while ghrelin downregulation in the stomach may be an appropriate adaptation to obesity, by potentiating the central actions of signals that induce negative energy balance, and reducing gastric acid secretion and motility, it is also possible that low ghrelin secretion might have less desirable effects including contributing to the maladaptive reduction of GH secretion characteristic of the obese state.

### XIII THE PITUITARY-THYROID AXIS IN OBESITY

Although hypothyroidism can present with weight gain, the hypothalamic-pituitary-thyroid (HPT) axis is not considered to play a major role in the etiology of obesity. However, thyroid hormone is an important regulator of genes for energy homeostasis (133–137). An additional direct nongenomic effect of 3,5-di-iodothyronine on mitochondrial respiration has been suggested (138). During fasting, overfeeding, and in obesity, adaptations occur at all levels of the HPT axis. The availability of free hormone measurements and sensitive thyrotropin-stimulating hormone (TSH) assays over the past two decades has aided research in this area. Although a study in obese adults found no change in free thyroid hormone levels (139), a study of lean and obese children reported that the median TSH and

thyroid hormone levels were elevated in obese subjects, although still within the reference ranges (140). Increased TSH and decreased prolactin responses to TRH are also seen in obesity (141), suggesting central upregulation. Levels of TSH also correlate with body fat and plasma leptin in obese subjects (142), consistent with central upregulation. Experimental data in humans confirm that the HPT axis is under nutritional control. Overfeeding increases total levels of thyroid hormone and reduces levels of reverse-T<sub>3</sub>, (143), whereas fasting reduces free T<sub>3</sub> and free T<sub>4</sub> levels in obese subjects (144). Although 5'-deiodinase activity is under nutritional control and regulates T<sub>4</sub>-T<sub>3</sub> conversion, the fasting-induced fall in T<sub>3</sub> is mainly due to reduced thyroid secretion (145). Therefore, the main nutritional and obesity-related changes in the HPT axis occur centrally. The mechanism for this involves the action of leptin in the arcuate nucleus on POMC and NPY-containing neurones (146,147). Thus, the HPT axis makes appropriate adaptations to fasting, defending body weight and muscle mass. As with other endocrine mechanisms, the HPT axis has little capacity for the reverse adaptation in the obese state. Thyroid hormones have attracted interest in obesity treatment, but their primary effect is to reduce lean rather than fat mass (148). This and other side effects confirm that therapeutic hyperthyroidism is not a treatment option for obesity.

### XIV CONCLUSIONS

Obesity causes many endocrine adaptations and defects related to fuel metabolism, energy storage, and reproduction (Fig. 2). Overt endocrine causes of

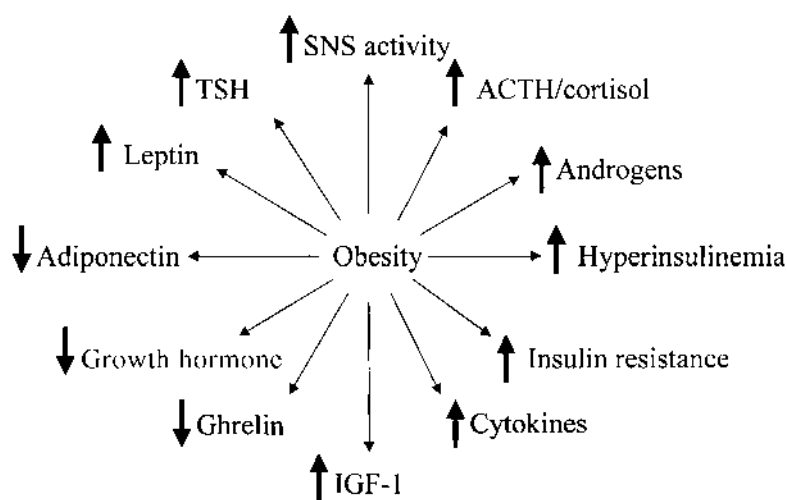

Figure 2 Endocrine consequences of obesity.

obesity are unusual, but advances in genetics are identifying a small number of genes predisposing to obesity. The endocrine adaptations to obesity, with the exception of glucocorticoids and sex steroids, and their effect on fat distribution, are not important in the causation of obesity. They may, however, contribute to the perpetuation of corpulence. Such endocrine adaptations have evolved to store fuel efficiently during times of plenty and to defend the lean body mass in times of famine. Unfortunately, they have little capacity for reverse adaptations in the face of continuous positive energy balance and consequential obesity.

## Endocrine Determinants of Fat Distribution

**Renato Pasquali, Valentina Vicennati, and Uberto Pagotto**

University of Bologna and S. Orsola-Malpighi General Hospital, Bologna, Italy

### I INTRODUCTION

Obesity is a heterogeneous disorder with wide variations in risks for complicating diseases. The recognition of the marked differences between excess fat localized in different parts of the body has markedly increased the knowledge of mechanisms by which metabolic and cardiovascular risk factors and diseases aggregate to specific phenotypes of obesity. At the same time, emerging scientific interest has increased our understanding of the main metabolic and hormonal factors involved in the pathophysiology of different obesity phenotypes.

This chapter will focus on the concept of adipose tissue as an endocrine organ, the regulation of the lipolytic/lipogenetic balance, the physiology of hormone regulation of different adipose tissue depots, and the role of hormonal derangements in the pathophysiology of different obesity phenotypes, particularly the abdominal phenotype.

### II ADIPOSE TISSUE AS AN ENDOCRINE ORGAN

Adipocytes are well known for their essential role as triglyceride depots, from which energy is called forth at times of need in the form of free fatty acids (FFAs) and glycerol. However, in the past few years, it has been definitively established that adipose tissue may also act as an endocrine organ. In fact, adipocytes express and secrete a number of peptidergic hormones and cytokines, which help to maintain homeostasis; vasoactive

peptides, whose proteolytic products regulate vascular tone; and leptin, which plays a central role in regulating energy balance (1). Adipose tissue can also produce active steroid hormones, including estrogens and cortisol, by conversion of androgen precursors and inactive glucocorticoids, respectively. Through such secreted products, adipocytes may deeply influence local adipocyte biology, as well as systemic metabolism at sites as diverse as brain, liver, muscle, pancreatic  $\beta$ -cells, gonads, lymphoid organs, and systemic vasculature (2).

Adipose tissue is also tightly regulated in its differentiation process and in its metabolic functions by many hormones. Each hormone has its own peculiar effect, according to the receptor expression pattern, to gender and age, and to the different adipose tissue sites. These effects are particularly related to regulating the balance between fat accumulation (lipogenesis) and breakdown (lipolysis). There are several differences in the balance between lipogenesis and lipolysis among adipose tissues located in subcutaneous or visceral sites. These effects mainly depend on the activity of lipoprotein lipase and hormone-sensitive lipase, respectively.

### III FUNCTIONS OF ADIPOSE TISSUE: LIPOGENESIS AND LIPOLYSIS

#### A Lipoprotein Lipase: Lipogenesis

Lipoprotein lipase (LPL) is an extrahepatic enzyme responsible for the hydrolysis of triglycerides into chylomicra and very low density lipoprotein (VLDL), and

controls the rate-limiting step in the removal of FFAs from the bloodstream. LPL is mainly located at the endothelial surface, and at the level of adipose and muscular tissues as well (3). In vitro studies have shown that adipocyte precursors have no LPL activity during their growth phase in culture, whereas a high enzymatic activity, correlated with adipocyte size, is noticeable during postconfluence differentiation of the cells (3). Insulin, glucocorticoids (GCs), catecholamines, interleukin (IL)-6, IL-1, and other factors differently modulate LPL activity in the various fat depots. The regulation of LPL secretion is related to posttranslational changes in the LPL enzyme at the level of Golgi cisternae and exocytotic vesicles (4). Interestingly, this enzyme displays a specific gender difference (4), due to the different types of receptors expressed by adipocytes in both sexes. In men, LPL activity, measured by radiolabeled triglyceride uptake, is 50% higher in the omentum than in abdominal subcutaneous fat (5). On the contrary, an opposite pattern is observed in women, in whom the omental adipocytes are smaller and the activity of LPL located in abdominal fat depots is lower than that in subcutaneous fat, regardless of the presence of obesity (4).

#### **B Hormone-Sensitive Lipase (HSL): Lipolysis**

Adipose tissue releases energy in response to the body's demands (6). Lipolysis in adipose tissue has been extensively investigated in vivo and in vitro because it is easy to quantify the end products such as FFAs and glycerol induced by the lipolytic process. A specific hormone binding to plasma membrane-bound receptors initiates the lipolytic cascade. These receptors are coupled with a G-protein, which may have both stimulatory (Gs) and inhibitory (Gi) effect. Gs proteins are able to activate the intracellular catalytic moiety of adenylyl-cyclase converting ATP to cyclic AMP (cAMP). cAMP binds to the regulatory subunit of protein kinase, releasing an active catalytic subunit able to phosphorylate and activate HSL, the rate-limiting enzyme of lipolysis (6). The Gi inhibits the breakdown of ATP into cAMP, thus blocking the lipolytic cascade. Only insulin and catecholamines have marked acute effects on lipolysis. Insulin inhibits lipolysis (7) whereas catecholamines have dual effects: stimulation through different  $\beta$ -receptors and inhibition through  $\alpha_2$ -receptors (8). HSL activity is also increased by ACTH, glucagon, TSH (3), cAMP (6), and caffeine and teophylline (3). It has been shown in vitro that HSL mRNA and activity are higher in subcutaneous than in omental fat cells. Moreover, subcutaneous adipocytes are larger in the subcutaneous than

in the omental region, and the lipolysis rate is significantly correlated to fat cell size regardless of either the region of origin or gender, indicating that the regulation of HSL activity is to a large extent dependent on fat cell size (9). Antilipolytic parahormones such as adenosine and prostaglandins, which are produced locally, are also of importance for the regulation of lipolysis in humans.

### **IV PHYSIOLOGY OF HORMONE REGULATION OF BODY FAT DISTRIBUTION**

#### **A Insulin**

The adipocyte is a highly insulin-responsive cell type. In fact, insulin is a critical regulator of virtually all the metabolic step aspects of adipocyte physiology (2). Insulin promotes adipocyte triglyceride storage by several mechanisms, including fostering the differentiation of preadipocytes to adipocytes and stimulating glucose transport and triglyceride synthesis, as well as inhibiting lipolysis in mature adipocytes. By stimulating LPL activity in adipose tissue insulin also increases the uptake of fatty acids derived from circulating lipoproteins (Table 1). Insulin's metabolic effects are mediated by rapid changes in protein phosphorylation and function, as well as by changes in target gene expression (2). Insulin and GCs represent the main physiological stimulants of the LPL activity; their association plays an important role in the regulation of body fat topography. When omental adipose tissue, resistant to insulin action, is exposed to a combination of insulin and dexamethasone for 7 days, a large increase in mRNA LPL is observed (10). GLUT4 is the main insulin-responsive glucose transporter and is located primarily in muscle cells and adipocytes (11,12). In the presence of insulin, GLUT4 is translocated from intracellular storage to the plasma membrane, leading to a rise in the maximal velocity of glucose transport into the cell (12). The initial molecular signal for insulin action involves the activation of the insulin receptor substrates (IRSs), the activation of phosphoinositide 3' kinase (PI3K), leading to the translocation of GLUT4 to the plasma membrane (13–15). Whereas activation of PI3K is necessary for full stimulation of glucose transport by insulin, emerging evidence suggests that the other metabolic effects of insulin might be mediated by another pathway with differential sensitivity to insulin (14). For example, the antilipolytic effect of insulin requires much lower insulin concentrations than stimulation of glucose transport. Hence, even in insulin-resistant states in which glucose transport is impaired, sensitivity to insu-

**Table 1** Comparison of Lipolysis and Lipogenesis in Omental and Subcutaneous Fat in Nonobese and Obese Individuals (Insulin and Catecholamines Are the Most Important Hormones in the Regulation of Lipolysis)

| Omental fat            |  | Subcutaneous fat         |                          |
|------------------------|--|--------------------------|--------------------------|

lin's antilipolytic effect is relatively preserved, resulting in maintenance or expansion of adipose stores.

Insulin also plays an important role in the regulation of leptin secretion, even though there are discordant data in the literature. In fact, it has been shown that both acute (hours) and chronic (days) administration of insulin in vivo or in vitro increases *ob* mRNA in rodents and humans (16–19). On the contrary, Sinha et al. did not find any correlation between 24-hr profiles of circulating leptin and insulin levels (20). However, this does not exclude the possibility that chronic hyperinsulinemia, which characterizes obesity, may cause and maintain an elevated leptin expression. It has been shown that the fasting condition or the diabetic state, both of which are known to decrease the circulating insulin level, causes a dramatic reduction in leptin expression, as indicated by changes in the level of the leptin message on adipose tissue (16,21). This decrease can be rapidly, i.e., within hours, reversed by refeeding or insulin administration (16,21). It is likely that insulin acts directly on the adipocyte, rather than indirectly via hormones produced by remotely located tissue, because leptin mRNA level is markedly increased by insulin in epididymal fat explants and adipocyte cell lines (22). Insulin has a favoring role on cortisol-induced LPL activation. These combined actions might, at least in part, explain the different LPL activity in visceral than subcutaneous fat depots, considering that abdominal fat shows a higher glucocorticoid receptor density (23).

## B Catecholamines

Catecholamines may specifically activate four adrenergic receptors:  $\beta_1$ ,  $\beta_2$ ,  $\beta_3$ , and  $\alpha_2$ , all members of the super family of G-protein-coupled receptors (24). There are significant species differences in adrenergic receptors, and significant differences in affinity of each receptor for the ligand. The order of affinity of the adrenergic receptors is  $\alpha_2 > \beta_1 \geq \beta_2 > \beta_3$  for norepinephrine (25), and  $\alpha_2 > \beta_2 > \beta_1 > \beta_3$  for epinephrine (24). The biological significance of the presence of three different  $\beta$ -receptors in adipocytes is unclear but it has been suggested that each receptor subtype might display a different signaling role (26). All three  $\beta$ -receptors are Gs coupled and all may activate adenylyl cyclase. Only  $\beta_3$ -receptors have been shown to also interact with Gi in adipocyte membranes, suggesting a different crosstalk of these receptors with inhibitory receptors (26).  $\beta_1$ -receptors, which are more sensitive to catecholamines and desensitize rapidly, may mediate acute effects of low level catecholamine stimulation. On the other hand,  $\beta_3$ -receptors, which require higher levels of catecholamines to be activated and are more resistant to desensitization, deliver a more sustained signal (27, 28). The presence of the inhibitory  $\alpha_2$ -receptor provides the cell with the opportunity of dual regulation of cyclase activity. It has been demonstrated that gluteal adipocytes isolated from females have more  $\alpha_2$ -receptors than adipocytes from males (29). Microdialysis

experiments suggest that the  $\alpha$ 2-adrenoreceptors may regulate lipolysis in the resting phase, while the  $\beta$ -receptors regulate lipolysis during exercise (30). Males have a larger visceral fat cell volume, which seems to be associated with a decrease in  $\alpha$ 2-receptors and an increase in the  $\beta$ 3-adrenoreceptor function (31). These differences may account for gender-specific differences observed in the balance between lipolysis and lipogenesis. In vitro studies have shown a different regional sensitivity to both sympathetic nervous system (SNS) and insulin action. In both genders, the subcutaneous abdominal adipocytes have higher  $\beta$ 1- and  $\beta$ 2-adrenoreceptor density and sensitivity and a reduced  $\alpha$ 2-receptor affinity and number than the femoral and gluteal adipocytes (7). Thus, femoral and gluteal depots show a lower lipolytic response to catecholamines than subcutaneous depots (30). On the other hand, visceral adipocytes are equally sensitive to both catecholamine-induced stimulation and inhibition of lipolysis, but they are less sensitive to the antilipolytic effect of insulin when compared to the subcutaneous abdominal or femoral adipose tissue (31,32). Thus in visceral adipose tissue there is a higher turnover of lipids than in the other fat depots, with greater sensitivity to catecholamine-induced lipolysis and decreased sensitivity to insulin antilipolysis (7) (Table 1).

### C Glucocorticoids

Glucocorticoid receptors (GCRs), located at intracellular level, function as transcription factors by inducing and/or repressing the expression of a host of target genes. The GCRs are members of the steroid-thyroid intracellular receptor superfamily. The ligand binding to receptors is modulated by "prereceptor" metabolism (33). Recently, it has been demonstrated that pre-receptor metabolism of GCs is an important determinant of tissue-specific responses. There is strong evidence for such a role for  $11\beta$ -hydroxysteroid-dehydrogenase ( $11\beta$ HSD) enzymes. In adipose tissue,  $11\beta$ HSD isoform type 1 is involved in the conversion of cortisone to cortisol. In human adipocyte culture,  $11\beta$ HSD1 activity is higher in the omental than in the subcutaneous fat (23) and GCRs show a regional difference in density, being higher in visceral fat depots (23). In vitro studies have shown that cortisol induces the LPL activity in human adipose tissue (34) and that RU486, a glucocorticoid receptor antagonist, induces an efficient inhibition of cortisol-induced LPL expression (35,36). The cortisol effects on LPL in human adipose tissue are dependent on insulin. LPL is efficiently expressed in a dose-dependent manner, and

is apparently a combined effect of transcription of the LPL gene and a stabilization of enzyme activity (35,36). Abdominal adipose tissue shows a higher expression of cortisol-induced LPL. Visceral adipose tissue has not yet been examined with respect to LPL activity and expression, but the high density of the GCRs (35,36) in visceral adipose tissue strongly suggests the possibility that the expression of LPL by cortisol is higher in visceral than in subcutaneous adipose tissue. Cortisol is also involved in the regulation of lipolysis. In the presence of insulin, when LPL activity is efficiently expressed, catecholamine-induced lipolysis is inhibited by cortisol (34). Finally, it has been demonstrated both in animal and human adipose cell lines that GCs are involved in the regulation of leptin secretion (17). In fact, glucocorticoids stimulate ob gene expression both in cultured explants of human adipose tissue (37) and in humans (38). Treatment of normal rats with different types of GCs at catabolic doses rapidly induces leptin expression in adipose tissue followed by a concordant decrease in body weight gain and food intake (39). Exposure of isolated rat adipocytes to dexamethasone was reported to increase leptin mRNA four- to eightfold within hours as well as leptin secretion (40).

### D Androgens

Male sex steroid hormones play an important role in the determination of body fat distribution and pattern of obesity. It is well known that androgens bind specific intracellular receptors. Androgen receptors (ARs) have been shown to be present in a very low level in hamster and human adipocytes (41). On the contrary, high levels of ARs have been described in male rat and human preadipocytes (42). Moreover, the number of ARs is more abundant in preadipocytes derived from abdominal than from subcutaneous fat deposits (43). These site-related differences in AR distribution between different fat depots constitute the rationale to explain divergent differentiation processes and metabolic responses observed between intra-abdominal and subcutaneous adipose tissues. Importantly, stimulation with androgens seems to upregulate the expression of their own receptor (42). Androgens stimulate lipolysis in adipose tissue. In primary culture of rat preadipocytes, chronic stimulation with androgens induced an antiadipogenic effect (43). In males, administration of testosterone (T) was followed by a reduction in LPL and FFA uptake in abdominal but not in subcutaneous adipose tissue (44). It is worth mentioning that growth hormone (GH) presence largely contributes to developing the full androgen

action at the level of fat depots. In conclusion, the final effect of androgens is a mobilization of lipids which induces a reduction of visceral fat.

### E Progesterone and Estrogens

Little is known about the effect of progesterone on fat distribution (45,46). Both isoforms of progesterone receptors (PR-A and PR-B) have been detected more in the stromal-vascular cells than in the adipocytes (45), being strikingly different from estrogen receptors which are mainly localized in the adipocytes (47). This different cellular distribution, recalling that reported at the level of the uterus endometrium (48), points to a complex interaction between estrogen and progesterone in modulating adipose tissue differentiation and function.

Estrogens bind with similar affinity to two different types of receptors, named estrogen receptor (ERs) ER $\alpha$  and ER $\beta$ . However, as observed in many organs, the activation of each receptor is supposed to mediate different transactivating properties (49). ERs in adipose tissue have only recently been documented, early studies being unable to detect ER (33,50,51). The development of more sensitive assays has made it possible to detect ER $\alpha$  mRNA, protein as well as specific estrogen binding sites in human subcutaneous adipose tissue (51,52). More recently, also ER $\beta$  mRNA has been found in human subcutaneous tissue (52). Altogether these findings clearly indicate that adipose cells are targets for estrogen actions. These data have been reinforced by functional studies in animal models. In rats, ovariectomy leads to an increase in body fat mass, which is reversible after estradiol (E<sub>2</sub>) administration (53). The definite proof that the effects mentioned above must be attributed to the ER activation is provided by the studies on mice in which ERs have been knocked out by genetic disruption. After sexual maturation, female mice having homozygous either ER- $\alpha$  or both subtypes deletion showed an increase in total body fat and enhanced serum leptin levels, demonstrating that ER $\alpha$  is responsible for the obese phenotype (54). Importantly, a second paper adopting the same molecular strategy and similar animal models detected the same phenotype also in male mice, indicative of the importance of ER $\alpha$  for normal development and function of adipose tissue in both genders (55). Estrogen replacement in ovariectomized animals resulted in decreased LPL enzyme activity (56).

In women, studies of the effects of hormone replacement therapy on LPL activity levels have been somewhat contradictory. Rebuffé-Scrive et al. (57) showed that the oral administration of sequential combination

of estradiol valerate and levonorgesterol to postmenopausal women significantly increased the adipose tissue LPL activity, but data about the effect of estrogens alone were missing from that study. In contrast, Iverius et al. (58) showed an inverse correlation between serum E<sub>2</sub> levels and adipose tissue LPL levels in obese women. Adipose tissue is one of the main sites of E<sub>2</sub> interconversion into estrone, particularly the gluteofemoral region. Price et al. (59) showed that the effect of female sex steroids is different depending on the menopause status. In fact, in premenopausal women progesterone is responsible for the stimulation of LPL activity, with deposition of adipose tissue in the gluteofemoral area rather than the abdominal region. On the contrary, in postmenopausal women progesterone production declined, and localized production of estrone predominates, with a decrease in LPL activity. Because estrone production is higher in the gluteofemoral region, LPL activity decreases in this area to a greater extent than does activity in the abdominal region. Thus, this change in activity is associated with abdominal deposition of body fat. After all, the effects of estrogens partly depend on those of androgens. However, to date, there is very little information on the mechanisms by which androgens and estrogens act separately and which cellular and molecular mechanisms are involved in the differentiation of adipose tissue morphology and function between the sexes.

### F Thyroid Hormones

Thyroid hormones have multiple catabolic effects on adipocytes by interacting with the adrenergic receptor signal transduction system (8). Increased concentrations and appearance rates of plasma nonesterified fatty acids (NEFA) and glycerol reflect this action (60). The mechanisms of thyroid hormone action on lipolysis *in vitro* is unclear. The increased lipolytic rate produced by thyroid hormones *in vivo* might be related to the increased subcutaneous blood-flow (60) or to a modification of the lipolytic action of catecholamines; it is known that in the hyperthyroid state there is an increase in the total number of  $\beta$ -adrenoreceptors ( $\beta$ 1 and  $\beta$ 2), unaltered function of the  $\alpha$ 2-receptors and enhancement of the lipolytic response to catecholamines in gluteal fat (61,62). However, recovery from hyperthyroidism affects visceral and subcutaneous fat differently, since Lonn et al. (63) showed that during the first 3 months of therapy there was an increase of visceral fat, whereas only after 12 months of therapy has an increase of subcutaneous adipose tissue been described (63). On the other hand, there are data show-

ing that in the hyperthyroidism state, muscle LPL activity is increased whereas adipose tissue LPL is unchanged (64). These apparent discrepancies clearly indicate the need for further studies on this topic. Additional studies are also needed to investigate the role of the hyperthyroid state on human body fat regulation and fat distribution.

## G GH

It is known that GH exerts its action mainly by inducing insulinlike growth factor (IGF-I) release from the liver; this growth factor is consequently believed to mediate the physiological effect of GH on the different target organs. However, GH is also able to directly affect some distinct target tissues such as adipose tissue. It has been known for many years that both rodent and human adipocytes express GH receptors (65). It is worth mentioning that human adipose tissue also expresses the splice variant (1–279) of the GH receptor at a high level (66), encoding for an isoform having intact extracellular and transmembrane domains but lacking more than 90% of the intracellular domain. This variant has no signaling capacity, but can inhibit GH action mediated by wild-type receptor in a dominant negative manner. However, the significance of this finding is at present still unclear. In rodent and human adipose tissue, GH exerts a lipolytic action either directly, by stimulating basal lipolysis (67), or indirectly, by influencing the ability of fat cells to respond to lipolytic hormones such as catecholamines (68).

At molecular level, GH is thought to increase lipolysis by increasing HSL expression and phosphorylation (69), by upregulating  $\beta$ 3-adrenergic receptor level (70), by inhibiting Gi protein (71), and/or by preventing insulin-induced antilipolysis. Recently, new analogs of GH have been provided and tested in animals. These compounds have specific and discrete functional domains of GH. Therefore, there is now evidence supporting the concept that some discrete structural domains within GH might be responsible for the different metabolic functions of the intact GH. Importantly, one of these compounds (AOD-9401) is composed of the carboxy-terminal fragment of the GH molecule and it appears to mainly regulate the lipid metabolism without being associated with alterations of the glucose metabolism as the whole peptide is. In rodents, this compound was able to reduce body weight and when assessed in adipose tissue in culture AOD-9401 significantly reduced lipogenic activity and increased lipolytic activity (72). Further in vivo studies are needed to definitively prove the mode of action of

this compound; however, this preliminary report may open new avenues for the full comprehension of GH interaction in adipose tissue. Even more interesting information, at present lacking, will be provided in the future by the use of the recently developed drug pegvisomant, which disables the functional dimerization of the two GH receptors involved in the signal transduction pathway (73).

## H Synthetic GH Secretagogues and Ghrelin

Growth hormone secretagogues (GHSs) are compounds able to stimulate GH release by parallel routes to those used by GHRH (74). In 1996, a specific receptor for these peptides was cloned and localized in different central and peripheral organs (75), and a few years later ghrelin, an endogenous ligand for this receptor, was discovered (76). The most important source of production of ghrelin is the stomach, suggesting that this peptide may act as an endocrine signal from gut to hypothalamus. Recently, ghrelin has been shown to play an important role in the development of obesity (77). Interestingly, these data were anticipated by data in which also GHSs were shown to enhance lean body mass and bone mass (78). However, it was difficult to discern whether the stimulatory effect of GHSs on food intake or that on GH secretion prevailed in determining changes in body composition. In fact, chronic stimulation of food intake by GHSs may result in increased body fat, whereas chronic stimulation of GH may result in reduction of body fat, GH being a lipolytic hormone. Recently, the usage of ghrelin in GH-deficient mice (lit/lit), has clearly confirmed that ghrelin displays a GH-independent effect on body weight increasing the fat mass (78). This adipogenic effect is brilliantly mirrored by the simultaneous increased level of circulating leptin, whereas it is well known that GH itself downregulates leptin levels. The precise mechanisms by which ghrelin or GHSs induces adiposity are still unclear, although it has been suggested that reduced levels of ghrelin may represent a physiological adaptation to the positive energy balance associated with obesity (79).

## I Leptin

Leptin, a 16-kDa protein, is the well-known product of the *ob* gene, mainly synthesized by adipose cells and secreted into the bloodstream (80). Leptin was discovered in genetically obese rodents (*ob/ob* mice), which are unable to produce an anorexic factor. Correction of leptin deficiency in these animals causes a marked

reduction in food intake and a normalization of the obesity syndrome (81). The role of leptin is to control food intake and energy metabolism. Leptin presents structural similarities to the cytokine family (82). Leptin receptors (OB-Rs) have been found at the level of hypothalamus, the brain center responsible for satiety (83). However, OB-R are not confined to the brain but exhibit a widespread distribution, including liver, heart, kidneys, lungs, small intestine, spleen, pancreas, and adipose tissue (83). The OB-Rs belong to the class I cytokine receptor family (84). The receptors have an extracellular domain, a transmembrane domain, and a variable intracellular domain characteristic for each of the five isoforms. OB-Rs act through Janus kinases (JAK) and signal transducers and activators of transcription (STAT). JAK proteins are phosphorylated, thus activating the translocation to the nucleus and stimulation of transcription (84). It has been shown that omental adipocytes have a lower leptin mRNA expression than the subcutaneous fat (85). There is evidence of a direct autocrine/paracrine effect of leptin on the lipolytic activity of isolated adipocytes (85). In addition, leptin has been shown to repress acetyl-CoA carboxylase gene expression, fatty acid synthesis, and lipid synthesis, biochemical reactions that contribute to lipid accumulation without the participation of centrally mediated pathways. Thus, leptin appears to be involved in the direct regulation of adipose tissue metabolism by both inhibiting lipogenesis and stimulating lipolysis (85).

## J IL-6

Similarly to leptin, IL-6 binds class I cytokine receptors, and in this way activates JAK and STATs. The IL-6 receptor expression pattern in the different fat depots localization is still unknown. IL-6 circulating levels are positively correlated with body mass index (86); this finding supports that notion that adipose tissue has to be considered a main reservoir of this cytokine. It has in fact been proposed that one-third of circulating IL-6 derives from fat cells (87). IL-6 is released from subcutaneous adipose tissue and three-fold more from visceral depots (87,88). However, cells other than adipocytes, such as fibroblasts, immune cells, and vascular cells composing the whole architecture of adipose tissue, constitute the main source of IL-6 (88), making it possible to speculate a mixed autocrine and paracrine role of this cytokine. However, since the liver is the direct target of the venous drainage from omental fat depots, the metabolic impact of IL-6 produced by omental adipose tissue

might be of pathophysiological relevance for alterations in lipid synthesis and metabolism. IL-6 has been shown to increase triglyceride secretion in rat liver (89), so IL-6 secreted by omental depots may contribute to maintain hypertriglyceridemia associated with abdominal obesity. IL-6 decreases adipose LPL activity (90) and increases lipolysis (91). These effects have been correlated with the fat depletion occurring during cachectic states characterized by high circulating IL-6 levels (90). IL-6 production from adipose tissue can be stimulated by  $\text{TNF}\alpha$  (92) and catecholamines (93), whereas GCs downregulate its production (93). The hyperactivation of hypothalamic-pituitary-adrenal (HPA) axis and the increased cortisol turnover are features of the visceral obese state (see below). IL-6 is capable of directly activating this axis at all three levels (94), so IL-6 produced by the adipose tissue may act as a feedforward regulator of this axis, playing an important role in contributing to modulate the differential fat distribution that occurs in patients displaying HPA hyperactivation.

## K $\text{TNF}\alpha$

$\text{TNF}\alpha$  is involved in the induction of insulin resistance (95) and in the loss of body fat occurring in wasting disorders (96). In humans,  $\text{TNF}\alpha$  binds p60 and p80 receptors (97). Some authors found an increase in the expression of both receptors in obese subjects (98), whereas others detected only an increase of the p80 receptor (99). Activation of p80 stimulates differentiation in human preadipocytes, whereas p60 seems to induce the opposite effect (100). Soluble circulating  $\text{TNF}\alpha$  receptor subtypes, which have been detected in the bloodstream, are supposed to inhibit  $\text{TNF}\alpha$  action. Increased levels of both these soluble subtypes have been recently described in obese patients (98), whereas another report showed an *in vivo* release of soluble type 1 by human adipose subcutaneous tissue (101).  $\text{TNF}\alpha$  is produced in greater amounts by subcutaneous than visceral fat (95,102). However, a positive correlation has recently been shown in female subjects between circulating  $\text{TNF}\alpha$  levels and visceral obesity, which has been attributed to the higher lipolytic action occurring in this adipose tissue district (103).  $\text{TNF}\alpha$  expression and/or secretion positively correlates with hyperinsulinemia (100). By suppressing LPL,  $\text{TNF}\alpha$  exerts a prominent catabolic effect on the adipose tissue (100). Moreover,  $\text{TNF}\alpha$  is supposed to activate HSL, leading to lipid mobilization and an increased delivery of FFA to the liver (104).  $\text{TNF}\alpha$  is also able to inhibit leptin synthesis (105), confirming that a close interaction seems to occur

between the network of cytokines produced in adipose tissue and leptin.

## L Resistin

A new peptide named resistin has recently been identified in adipose tissue after a screening for genes induced during adipocyte differentiation. Resistin is specifically expressed in white adipose tissue, circulates in the serum, and can be downregulated by thiazolidinediones. Increased resistin circulating levels have been shown in mouse genetic and diet-induced forms of obesity. Insulin-stimulated glucose uptake in adipocytes was increased by using neutralizing resistin anti-

serum and resistin administration in mice was shown to reduce glucose tolerance and to decrease the sensitivity to the effects of insulin (106). Resistin is a member of tissue-specific resistin-like molecules (RELMs), and other components such as RELM $\alpha$ , which is a secreted protein abundant in white adipose tissue, or RELM $\beta$ , which is expressed in the gastrointestinal tract, have recently been described (107). Isoproterenol treatment was shown to reduce resistin expression in 3T3-L1 adipocytes via  $\beta$ -receptor activation (108). Thus, one may speculate that catecholamines may influence resistin expression more in visceral adipose tissue in which the concentrations of receptors are higher compared to subcutaneous adipose depots. Rather surprisingly,

**Table 2** Hormones and Other Factors Involved in the Regulation of Body Fat Distribution and Their Mechanisms of Action

| Hormones and factors     | Biological functions and mechanisms of action  |
|--------------------------|--|
| Insulin                  | Synergism with GC in increasing LPL activity. Reduced sensitivity of the visceral adipocytes on antilipolytic activity. Stimulation of leptin mRNA expression.   |
| Glucocorticoids (GC)     | GC receptors highly expressed, particularly in the visceral adipose tissue. 11 $\beta$ -HSD highly expressed in the visceral adipose tissue. Increased LPL activity (synergism with insulin). In the presence of insulin when LPL is efficiently expressed, catecholamine-induced lipolysis is inhibited by cortisol. Stimulation of leptin mRNA expression. |
| Androgens (testosterone) | Receptors highly expressed in the visceral adipose tissue. Stimulation of lipolysis and reduced LPL activity in males. These effects are counteracted by estrogens in females. Regulation of leptin mRNA expression.   |
| Estrogens                | Estrogen receptors (ERs) highly expressed in the subcutaneous gluteofemoral adipocytes. Inhibition of LPL activity, particularly in the subcutaneous fat. Gluteofemoral adipocytes preferentially transform estradiol to estrone (the most important estrogen after menopause in women).   |
| Progesterone             | Receptors found in the stromal-vascular cells. Increase of LPL activity.   |
| GH and related peptides  | Stimulation of basal and catecholamine-induced lipolysis. Increase of HSL activity. Variants may be involved in reducing lipogenesis and increasing lipolysis. Ghrelin seems to favor fat gain.  |
| Iodothyronines           | Stimulation of lipolysis (increased blood flow or synergism with catecholamines?). Increase of $\beta$ 1- and $\beta$ 2- and reduction of $\alpha$ 2-receptors.  |
| Catecholamines           | Lipolysis in the visceral adipose tissue highly stimulated ( <i>see Table 1 for different receptor functions in visceral and subcutaneous fat</i> ). Stimulation of IL-6 release from adipose tissue (differences between visceral and subcutaneous?).   |
| Leptin                   | Omental adipocytes have lower leptin mRNA expression than subcutaneous fat. Paracrine effects on lipolysis (stimulation) and lipogenesis (inhibition).   |
| IL-6                     | Released by the stromal-vascular cells in the visceral fat more than in subcutaneous fat. Decreased LPL activity and increased lipolysis. Downregulated by GC but exerts stimulation of the HPA axis (therefore it may regulate GB effects on the visceral fat).   |
| TNF $\alpha$             | Stimulation of IL-6 production from the adipose tissue P80 receptors involved in adipocytes differentiation. Production in different adipose tissue depots controversial (visceral < subcutaneous?). Inhibition of leptin synthesis. Activation of HSL (?) and release of FFA to the liver favored.  |
| Resistin                 | Expressed in the adipose tissue. Regulation by catecholamines more in the visceral than subcutaneous fat (?)   |

a recent report was not able to confirm the original data from Lazar's study (107) showing that resistin was severely decreased in the white adipose tissue of genetic obese mice and in animals with diet-induced obesity. Moreover, the same group showed that different PPAR $\gamma$  agonists stimulate resistin expression in two rodent models of type 2 diabetes (109). In conclusion, further studies are needed to fully clarify the potential implications of resistin and RELMs in the regulation of adipose tissue function and distribution. Table 2 summarizes all main hormonal actions and functions involved in the regulation of fat distribution in humans.

## **V BODY FAT DISTRIBUTION IN ENDOCRINE DISORDERS CHARACTERIZED BY HORMONE EXCESS AND DEFICIENCY**

### **A Cushing's Syndrome**

Cushing's syndrome is characterized by a redistribution of adipose tissue from peripheral to central sites of the body, mainly in the truncal region and visceral depots. This may occur as a result of the dual effect of GCs which on the one hand downregulate HPL and increase lipolysis, and on the other hand favor preadipocyte differentiation and stimulate substrates to gluconeogenesis and FFA to central fat. Centralization of visceral fat depots tends to be markedly reduced in patients with Cushing's syndrome after eradication of causes of cortisol excess, and this process can be successfully completed within 1–2 years after interventional surgical treatment at pituitary or adrenal level.

### **B Male Hypogonadism**

Hypogonadic males are characterized by increased amounts of visceral fat in both childhood and adult age, and these effects can be completely reversed after T replacement (110). Mechanisms by which T deficiency increases visceral fat depend on the lipogenetic/lipolytic balance in the visceral adipose tissue, due to a different receptor density compared to the subcutaneous tissue (see Sec. IV.D above). The same phenotype can be observed in elderly men, when an increase and redistribution of body fat occurs, with a specific tendency to a greater increase of the abdominal/visceral fat areas. The decline of T production and of circulating levels in elderly individuals plays a dominant role in this context. This is further supported by the decrease in fat mass,

particularly in the visceral depots, after long-term treatment with T, provided that physiological levels are achieved and maintained over time.

### **C Hyperandrogenism in Women**

More than 50% of women with the polycystic ovary syndrome (PCOS), the most common cause of hyperandrogenism in females, are overweight or obese. Moreover, most of them are characterized by abdominal fat distribution, particularly if they are obese. Obesity and the abdominal phenotype make it possible to distinguish a large cohort of PCOS women in which the metabolic syndrome is also frequently associated, even though this latter syndrome may also occur in normal-weight PCOS. Insulin resistance and hyperinsulinemia play a key role in the pathogenesis of hyperandrogenism. Mechanisms responsible for the great persistence of the abdominal phenotype in PCOS women largely depend on the coordinate effects of hyperinsulinemia and hyperandrogenism on fat balance. In addition, an excess of androgens may directly produce insulin insensitivity in the muscles by stimulating type II fibers, which are less sensitive to insulin and to increasing FFA efflux (36). Indirect evidence of the role of androgens in determining enlarged visceral fat in women is further supported by the fact that androgen administration in postmenopausal women increases visceral fat depots (111) and tends to reduce whole-body insulin sensitivity.

### **D GH Deficiency**

The profound lipolytic effect of GH have been clearly confirmed by in vivo studies in which GH replacement has been proposed in either children or adult GH-deficient subjects. In fact, several groups have demonstrated a redistribution of adiposity from the subcutaneous trunk to more peripheral regions after GH therapy (112) and a stimulation of FFA release (112). In general, fat redistribution after therapy has been associated with GH-induced reduction of the antilipolytic effect of insulin, which varies according to the fat depot localization.

### **E Acromegaly**

Pathological and inappropriate GH circulating levels characterize acromegaly. In patients affected by this disease there is a reduction in visceral adipose tissue, with an increase in lean body mass (113). The short-term

reduction in GH level obtained by octreotide treatment has been shown to reduce lean body mass (114).

## VI PATHOPHYSIOLOGY OF DIFFERENT OBESITY PHENOTYPES: THE ROLE OF HORMONES

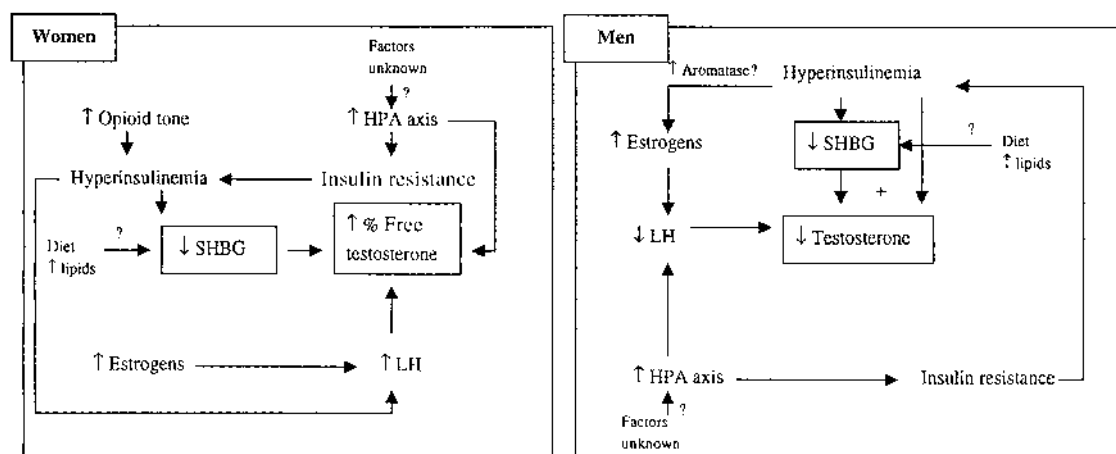

### A Sex Hormones in Women

It is well known that an increase in body weight and fat tissue is associated with several abnormalities of sex steroid balance in premenopausal women. Such alterations involve both androgens and estrogens and overall their carrier protein, sex hormone binding globulin (SHBG), which binds T and dihydrotestosterone (DHT) with high affinity and estrogens with lower affinity. Changes in SHBG concentrations lead to an alteration of androgen and estrogen delivery to target tissues. SHBG plasmatic levels are regulated by a complex of factors, including estrogens, iodothyronines, and GH as stimulating agents, and androgens and insulin as inhibiting factors (115). The net balance of this regulation is probably responsible for the SHBG concentration decrease in obesity, which is inversely related to the increase in body weight (115). Body fat distribution has been demonstrated to substantially affect SHBG concentrations in obese women. In fact, female subjects with central obesity usually have lower SHBG concentrations in comparison to their age- and weight-matched counterparts with peripheral obesity (116). This seems to be dependent on higher circulating insulin in abdominally obese women and on the inhibiting capacity of insulin on SHBG liver synthesis. Reduction of circulating SHBG determines an increase in the metabolic clearance rate of circulating SHBG-bound steroids, specifically T, DHT, and androstenediol (A-diol), which is the principal active metabolite of DHT (116). However, this effect is compensated for by a consequent elevation of production rates. Obesity also affects the metabolism of the androgens not bound to SHBG. In fact, both production rates and metabolic clearance rates of dehydroepiandrosterone (DHEA) and androstenedione (A) are equally increased in obesity (117,123).

The pattern of body fat distribution can regulate androgen production and metabolism to a significant extent. In fact premenopausal women with central obesity have higher T production rates than those with peripheral obesity (119). Accordingly, metabolic clearance rates of T and DHT are significantly higher in women with central than with peripheral obesity. The maintenance of normal circulating levels of these hor-

mones in obesity may tend to predict the presence of a sophisticated regulation, which can adjust both the production rate and the metabolic clearance rate of these hormones to body size. Owing to the greater reduction of SHBG concentrations, percentage free T fraction tends to be higher in women with central obesity than in those with peripheral obesity (116). An inverse correlation exists between waist to hip ratio (WHR) (or other indices of body fat distribution) and T or SHBG concentrations, regardless of body mass index (BMI) values (116). Therefore, a condition of "relative functional hyperandrogenism" appears to be associated with the central obesity phenotype in women. Androgens play an important role in determining body fat distribution in the female sex. Mechanisms of action have been previously discussed (see Sec. IV.D). This can explain the significant positive association between the abdominal phenotype and hyperandrogenism, as occurs particularly in women with PCOS (120). The observation that visceral fat accumulation occurs only in female-to-male transsexuals after oophorectomy suggests that the remaining estrogen production before surgery was in fact protective (121). Direct evidence of the action of androgens in women is also provided by a controlled study showing that exogenous androgen administration in obese postmenopausal women has been shown to cause a significant gain in visceral fat (as measured by CT scan) and a relatively greater loss of subcutaneous fat in comparison with placebo (111). Mechanisms leading to "functional hyperandrogenism" in obese women are depicted in Figure 1.

Obesity can also be considered a condition of increased estrogen production, since the estrogen production rate significantly correlates with body weight and the amount of body fat (118). Reduced SHBG concentrations may in turn lead to an increased exposure of target tissues to free estrogens. In addition, obesity is associated with a decreased formation of inactive  $17\beta$ -E<sub>2</sub> metabolites, such as 2-hydroxyestrogens, which are virtually devoid of peripheral estrogen activity, and a higher production of estrone sulfate, an important reservoir of active estrogens. Altogether, these alterations lead to an increased ratio of active to inactive estrogens as a final result. However, in spite of these alterations, blood estrogen concentrations are usually normal or only slightly elevated in both premenopausal and postmenopausal obese women (118). This finding may be attributed to the ability of an enlarged body fat to act as storage for excess formed estrogen, contributing in this way to maintain normal levels of circulating hormone. In addition, there are no systematic differences in the estrogen blood concentrations in women

**Figure 1** Schematic representation of sex hormone alterations in obese women (left panel) and men (right panel).

with different obesity phenotypes (122), although estrogen production rates have been found to be particularly increased in women with peripheral obesity. Together with the aforementioned protective effects of estrogens on visceral fat development, there is, however, evidence that they play a key role in the regulation of subcutaneous adipocytes, particularly during pregnancy and lactation (58). After menopause, a sudden decrease of estrogens occurs, due to the physiological ovarian failure. Whether the occurrence of menopause alters body weight and fat distribution remains controversial. In fact, while many women claim an increase in body weight during the transition period toward menopause and after menopause, most but not all studies (123) have shown that although the weight of postmenopausal women is greater than before menopause, this difference tends to disappear after adjusting for age values, thus suggesting that age and not the menopausal status per se is probably responsible for weight increase.

Some discrepancies have also been found with regard to the effects of menopause on fat distribution, since there are studies reporting that postmenopausal women had higher WHR values than premenopausal women, whereas others did not observe any effect (123). On the other hand, as discussed in a previous paragraph (see Sec. IV.E above), it should be taken into account that the androgen/estrogen balance differently regulates the adipose tissue morphology and function in the subcutaneous and visceral sites after menopause, thereby potentially favoring some change in the phenotype pattern. The lack of detailed studies investigating the specific role of each class of hormones could therefore explain the aforementioned discrepancies of

the effects of hormone replacement therapy in postmenopausal years.

Weight loss is associated with an increase of SHBG levels and the free androgen fraction in women with obesity (121). Moreover, in those with PCOS it not only improves insulin resistance but also the hyperandrogenic state, thereby restoring normal menses and improving fertility rate in a large part of them. Administration of insulin sensitizers such as metformin, added to a hypocaloric diet, further extends these effects and, additionally, seems to favor a greater reduction of the visceral adipose tissue depots (124). These beneficial effects appear to be dependent on the coordinated action of reduced androgen and insulin concentrations and improved insulin sensitivity.

Similar effects have been obtained by using thiazolidinediones, which are selective ligands for peroxisome proliferation-activated receptor (PPAR) $\gamma$ , a member of the nuclear receptor superfamily of ligand-activated transcription factor (125). Although their mechanisms of action are not yet fully elucidated, they markedly improved insulin-mediated glucose disposal (126) and, at high doses, may suppress basal hepatic glucose production. Studies performed in PCOS women using troglitazone (127) have demonstrated its capability to significantly improve insulin sensitivity, decrease fasting and stimulated insulin levels, reduce the degree of hyperandrogenism, and in several cases, improve spontaneous ovulation. On the other hand, there are studies suggesting that long-term treatment with thiazolidinediones may weakly but significantly increase body weight (128). This may not be surprising, since cell culture studies have demonstrated that after activation

of PPAR $\gamma$ , these compounds promote differentiation of pluripotent stem cells and preadipocytes into mature adipocytes (125). Whether changes in body fat occur in the same extent in both subcutaneous and visceral depots has not been clarified. This critical issue needs therefore to be defined by further long-term studies in both diabetic and non diabetic individuals.

Other agents, such as diazoxide, have been proved to selectively reduce hyperinsulinemia and hyperandrogenism in short-term studies performed in obese PCOS women (129). In the unique double-blind placebo-controlled trial performed so far, Alemzadeh and co-workers found that in a group of hyperinsulinemic obese patients, 8-week treatment with diazoxide (2 mg/kg BW) associated with a low-calorie diet reduced insulin levels, body weight, and body fat significantly more than placebo, without altering glucose tolerance (130). However, larger, long-term studies seem justified to evaluate the therapeutic effect of diazoxide, particularly in abdominal obesity.

In obese women with PCOS a weak but significant improvement of insulin resistance and hyperinsulinemia can also be achieved by antiandrogen administration. These effects have been observed regardless of the type of antiandrogen used (131). Preliminary data from our group, obtained in a 6-month study on a group of obese PCOS women, seem to be consistent with the possibility that a potent antiandrogen flutamide, when added to hypocaloric dieting and metformin, may further and selectively reduce visceral body fat by  $\sim 50\%$ , these effects being associated with a normalization of androgen levels (unpublished data). These findings further support the concept that androgens are an important determinant of the abdominal obesity phenotype in women.

## B Sex Hormones in Males

In contrast to what has been observed in obese women, in the obese male total and free T blood concentration levels progressively decrease with increasing body weight, as clearly exemplified in subjects affected by Klinefelter syndrome (132). Moreover, such a reduction is associated with a progressive decrease of SHBG concentrations (133). Spermatogenesis and fertility are not impaired in the majority of obese men. However, these parameters have been described to be reduced in subjects with massive obesity (132). Androstenedione and DHT circulating levels are usually normal or slightly reduced in obese patients (134). However, other C19 steroids can also be reduced in obesity (134). Similarly to what has been reported for women, in male obesity,

estrogen production rates are increased in proportion to body weight, and blood concentrations of all major estrogens, particularly estrone, have been described as normal (132) or only slightly elevated (115). Aromatase activity of the adipose tissue, responsible for active conversion of androgens into estrogens, may explain the altered estrogen metabolism in obesity. Alterations in gonadotropin secretion have also been described in male obesity. Obese men show a reduction of total luteinizing hormone (LH) secretion, probably due to impaired secretion of the gonadotropin releasing hormone at the hypothalamic level, producing a reduced LH secretory mass per secretory burst without any change in burst number (135). The absence of clinical signs of hypogonadism can be explained by the fact that the T freefraction represents only 2% of total T, and that obesity predominantly affects circulating bound T, owing to the concurrent decrease of SHBG production. Although T levels are inversely related to obesity, it is still under debate whether T correlates with fat distribution in male obesity. Some studies (136) found an association between T and WHR values, whereas others, using anthropometry or magnetic resonance, showed no correlation (137,138). This suggests that the relationship between sex steroids to WHR may be the result of the shared covariance of WHR and total adiposity, rather than a direct relationship. This reflects the evidence that obesity in males is invariably associated with a parallel increase in abdominal and visceral fat, meaning that the central distribution of body fat in males depends on the actual presence of obesity.

Other studies have confirmed that the reduction of C19 steroid precursors are predominantly associated with body fatness rather than with excess visceral fat accumulation (134). Glucuronic acid is able to conjugate steroids influencing their biological activity. Notably 3-androstenediol glucuronide (3A-Diol-G) levels were found to be significantly higher in obese men having a visceral phenotype (134). This association between 3A-Diol-G and visceral fatness suggests that an increased visceral adipose tissue corresponds to a state in which the steroid metabolism is altered. Glucuronide conjugates must therefore be considered a more appropriate marker of peripheral androgen metabolism than circulating free steroids.

Both SHBG and T are negatively correlated with insulin levels, even after adjusting for BMI and WHR values (137). Such an inverse relationship is due to the ability of insulin to inhibit hepatic SHBG synthesis in the liver (139). However, as has been demonstrated in women, particularly in those with PCOS (131), there are data consistent with a stimulatory role of insulin on T

production even in men (139). Therefore, reduced T levels in obese males appear to result from several complementary factors, including lower gonadotropin secretion and the balanced effects of insulin on SHBG (inhibition) and T (stimulation). Mechanisms leading to reduced T levels in obese men are depicted in Figure 1.

Weight reduction by both dietary intervention or surgical procedures can increase T and SHBG concentrations, provided substantial weight loss is achieved (115). When massively obese men restore a near-normal BMI, SHBG concentrations fall within the reference values for normal-weight individuals. Although there are no kinetic data on estrogen production following weight loss in obese men, it is presumable that estrogen metabolism and peripheral production improve as weight loss increases. Interestingly, the correction of the hypotestosteronemia by exogenous T replacement has been found to provide a beneficial effect not only by reducing body fat, particularly visceral fat, but also on all major parameters of the metabolic syndrome, by reducing hyperlipidemia and improving peripheral insulin sensitivity (140).

### C The GH/IGF-I Axis

Growth hormone is substantially reduced in obesity, mainly owing to a significant reduction of GH secretory burst mass in the pituitary (141). The entity of this alteration appears to be inversely proportional to the increase in body fat (132). Blunted GH secretion to all stimuli of GH release, including GHRH, insulin-induced hypoglycemia, L-dopa, arginine, glucagon, exercise, opioid peptides, clonidine, nicotinic acid, or states such as deep sleep, is a common feature in obese subjects (132). The mechanisms responsible for reduced GH levels in obesity are multiple and not yet fully clarified. It is known that GH metabolic clearance rate is increased in proportion to body weight, as demonstrated in monkeys (142) and humans (120). Moreover, an enhanced somatostatinergic tone may further contribute to the reduced levels of GH in obese patients (143). However, as mentioned above, other still unknown central factors may be hypothesized to be involved in the impaired GH secretion in obesity. Peripheral factors have also been implicated in contributing to reduce GH levels. The increase of FFA production characterizing obesity may inhibit basal GH secretion, by mechanisms independent of effects on somatostatinergic tone (132). Sex steroids, specifically T and E<sub>2</sub>, have positive effects on GH secretion, probably by influencing the pulsatile mode of GH release (139). Basal GH secretory bursts, which are

reduced in obesity, are positively correlated with E<sub>2</sub> and T concentrations (139), further indicating a close relationship between sex steroid imbalance and GH secretory dynamics in the obese state.

The role of IGF-I in obesity is still under debate. The normal growth of obese children, in spite of the fact that they have lower GH levels in basal conditions and after stimulatory testing, seems to suggest that IGF-I action in the target tissues for growth is indeed adequate for growth and development before, during, and after puberty (132). However, the finding that free IGF-I levels are elevated in obese subjects (144) makes it possible to speculate that, via an inhibitory feedback on GH secretion at pituitary level, IGF-I may take part in the decline in obesity-associated GH levels. Importantly, subjects with visceral obesity have reduced circulating IGF-I levels (132). Since insulin regulates IGF-I metabolism, stimulating the synthesis of IGF binding protein (IGFBP)-I, alterations in circulating levels of IGF-I in visceral obesity may reflect a prevailing hyperinsulinemia in the blood circulation.

The potent lipolytic activity attributed to GH levels may be of relevance taking into account the reduced GH levels in obesity. Therefore, an unbalanced lipogenetic condition might be responsible for the perpetuation of the obese state once established. In fact, obese subjects have elevated insulin levels as a consequence of the insulin resistance state with respect to carbohydrate metabolism, but the adipose tissue remains sensitive to the antilipolytic effects of insulin. Evidence from animal and human studies supports the hypothesis that GH administration in obesity may stimulate lipolytic pathways and can provide a valuable adjunct to diet in inducing weight loss. In GH-deficient children, many of whom are obese, GH administration reduces body fat (145). The same occurs in subjects with adult GH deficiency (146) and in elderly subjects who have undergone therapy with GH to increase lean body mass and improve fitness (32). Exogenous GH administration also reduces fat stores, particularly in the visceral deposits, in GH-deficient adult subjects (147). These effects can be additive to those dependent on diet restriction, but they may also occur in conditions of eucaloric intake (148). One limitation of GH administration is related to the possibility that long-term GH treatment worsens glucose tolerance and insulin resistance, although the contrary has been reported by some studies (147). Perhaps the administration of GH in a manner that stimulates normal physiological secretion rather than pharmacological doses would circumvent or lessen its effects on carbohydrate metabolism in the long term.

## D Glucocorticoids and the HPA Axis

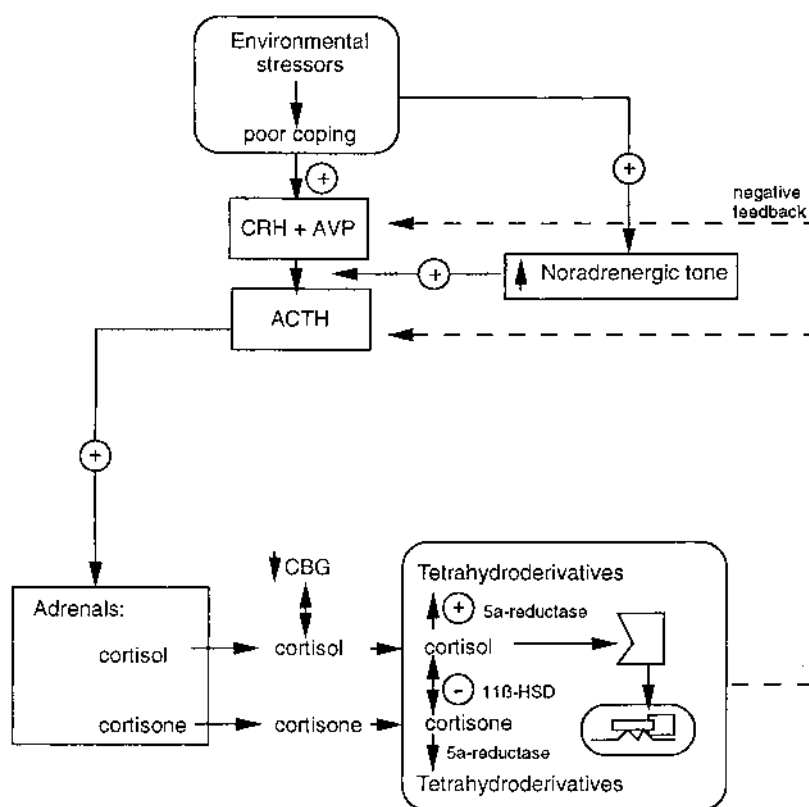

Cortisol excess may have a key role in the development of enlarged abdominal or visceral fat in obese individuals of both sexes. This derives from the combination of the effects produced by hyperinsulinemia, from the GH reduction and from the decreased (in male obesity) or increased (in female obesity) free androgen availability in peripheral tissues, which are the above-mentioned features of abdominal phenotype of obesity (149). Most studies found normal ACTH and cortisol levels in visceral obesity, although slightly reduced morning cortisol levels have been described by some authors (150). Visceral obese women had higher ACTH pulse frequency and lower ACTH pulse amplitude, particularly in the morning, despite similar mean ACTH basal concentrations, than women with peripheral obesity and normal weight controls (151). However, the dysregulation of the system in abdominal obesity has been more convincingly demonstrated by many dynamic studies, which showed high secretions of cortisol after laboratory stress test, elevated ACTH and cortisol secretion after administration of CRF alone or combined with arginine-vasopressin (AVP), and elevated cortisol concentrations after challenges with maximal or low-dose ACTH (152) in abdominal obese patients. This might indicate sensitized and/or hyperresponsive hypothalamic centers, pituitary as well as adrenal regulatory mechanisms, that result in slightly but inappropriately elevated net cortisol production, either continuous or episodic, in individuals with abdominal obesity.

Among the dynamics, dexamethasone suppression test has been proposed as the gold standard to discriminate between a normal and a pathological activation of the HPA axis. However, maximal suppression with dexamethasone cannot provide adequate information on the feedback sensitivity at both pituitary and suprapituitary levels. At variance, it has been suggested that the utilization of lower dexamethasone doses may give good insight into the individual feedback sensitivity of the HPA axis. Preliminary studies from Ljung et al. (153), performed in a group of men with different obesity phenotypes, found a blunted inhibition of cortisol secretion by submaximal (0.50 mg overnight) dexamethasone administration, thus suggesting a reduced sensitivity to inhibition by dexamethasone via downregulation of central glucocorticoid receptors. We recently performed an extensive study in a large cohort of obese and normalweight individuals by using different doses (0.0035 mg, 0.0070 mg, and 0.015 mg/kg BW) of dexamethasone administered orally at midnight. The results of this study showed that obesity had no effects

on cortisol and ACTH concentrations following each test, whereas sex and dexamethasone blood levels represented the main factors influencing the HPA axis suppressibility in both obese and normal weight individuals (154).

It has been speculated that alterations of the HPA axis activity may derive from a disruption of the regulatory mechanisms at central nervous system level. In this context, we have proposed that abnormal catecholaminergic regulation may take part in the hyperactivation of HPA axis. Catecholamines modulate CRH and ACTH secretion, particularly during acute and chronic stress challenges by activation of  $\alpha$ 1- and  $\alpha$ 2-adrenoreceptor subtypes. In particular, by inhibiting ACTH release in experimental animals and in humans (155),  $\alpha$ 2-adrenoreceptors may provide negative feedback mechanisms preventing an excess of glucocorticoid response to stressor stimuli. We found that yohimbine, an  $\alpha$ 2-adrenoreceptor antagonist, slightly but significantly reduced ACTH response to combined CRH + AVP challenge in normal weight controls, in comparison with that observed during the control test, whereas in obese women, particularly the abdominal phenotype, the response of ACTH was significantly increased (156). These different effects after  $\alpha$ 2-adrenoreceptor inhibition in the two groups suggest that obese women with abdominal body fat distribution may escape physiological  $\alpha$ 2-adrenoreceptor control, thus favoring inappropriate HPA axis excitation following appropriate neuropeptide stimulation.

Increased cortisol clearance (157), higher cortisol turnover, and altered cortisol metabolism in adipose tissue represent the main peripheral alterations of cortisol production and metabolism in obese patients (23,33). Many studies have shown that daily urine free cortisol excretion rate was significantly increased in subjects, particularly women, with abdominal body fat distribution (158). At variance, we recently found that nondepressed women with abdominal obesity were characterized by lower urinary free cortisol excretion rates, which is consistent with increased metabolic rates of cortisol. Theoretically, this could be due to multiple factors, including subtle abnormalities of cortisol transport, function, and metabolism. The concentrations of the corticosteroid-binding globulin, which carries cortisol into the bloodstream, may be reduced in the abdominal phenotype (150). Moreover, as stated above, visceral adipocytes show a higher number of GCRs than do subcutaneous adipocytes; the resulting increase of intracellular cortisol could therefore enhance cortisol metabolic clearance (158). In addition, alterations of enzymes such as 11 $\beta$ HSD1 and 5 $\alpha$ -reductase type 1 are

**Figure 2** Schematic representation of the HPA axis–noradrenergic system alterations in the pathophysiology of abdominal obesity and the metabolic syndrome. Exaggerated response to chronic stress factors and alterations in cortisol metabolism (whose causative mechanisms are still unknown), with compensatory neuroendocrine activation, may cooperate in determining HPA hyperactivation and cortisol hypersensitivity. Also shown is a schematic target cell, in which interconversion of cortisol and cortisone by 11 $\beta$ -HSD dictates access of GCs to receptors and subsequent regulation of target genes, encoding those responsible for negative feedback. Cortisol and cortisone circulate in similar free concentrations, although free cortisol is in equilibrium with a pool of cortisol bound to CBG and albumin. Symbols in circles indicate increased or decreased activity. (From Refs. 68,150.)

supposed to play a role in the alteration of HPA axis. Recent studies have provided evidence for an inhibition of 11 $\beta$ HSD1 in patients with increased central adiposity (158), similar to what was previously observed in patients with PCOS (159). The association between reduced 11 $\beta$ HSD1 activity and abdominal obesity should not, however, be surprising, since high doses of insulin inhibit this enzyme's expression (160). In addition, increased 5 $\alpha$ -reductase type 1 activity, as indicated by an increased urinary excretion rate of 5 $\alpha$ -tetrahydrocortisol (161), has also been reported in abdominal obesity. This may further contribute to increased catabolism of cortisol in extra-adrenal tissues. At present, no studies have investigated the effects of pharmacological or behavioral manipulations in order to normalize HPA responsiveness and/or derangements in cortisol metabolism in patients with the abdominal

obesity phenotype of both sexes. Both central and peripheral mechanisms responsible for altered HPA axis activity in the abdominal obesity phenotype are represented in Figure 2.

## VII SUMMARY AND CONCLUSIONS

The recognition that adipose tissue has endocrine properties and represents a main target for hormone effects has reinforced research in this direction, and over the years new findings have enormously increased our knowledge on the main mechanisms of regulation of some functions of the human body, including energy balance and body composition, in both the physiological state and in diseases. Mechanisms of regulation of the differentiation and the lipogenetic/lipolytic balance

in the different adipose tissue depots involve a list of hormones, cytokines, and neuropeptides not yet completely defined, acting via endocrine, paracrine, and autocrine pathways (Table 2). Among the hormones, alterations of the hypothalamic-pituitary-gonadal axis, the GH/IGF-I axis, and the HPA axis, acting in concert and with the modulatory role of insulin and the noradrenergic system, appear to play a dominant role in the pathophysiology of the abdominal obesity phenotypes in both females and males. Moreover, the endocrine axis appears to be strictly interconnected with leptin regulation and function, both in the adipose tissue and at neuroendocrine sites. An exciting area of investigation is further represented by the crosstalk between other locally acting cytokines, particularly  $\text{TNF}\alpha$  and IL-6. The recognition of endocrine and metabolic derangements in different obesity phenotypes may be of importance in the definition and categorization of patients and in defining the pathophysiology of associated comorbidities, particularly type 2 diabetes, cardiovascular diseases, and hormone-dependent cancers. In addition, these findings pave the way for more sophisticated potential applications of hormone replacement therapy, particularly with regard to the treatment of the visceral phenotype of obesity.

University of Nottingham Medical School, Nottingham, England

### I INTRODUCTION

The sympathetic nervous system (SNS) is an important component of the autonomic nervous system, and thus plays a major role in the maintenance of body homeostasis. The SNS is of particular importance in the control of the cardiovascular system and of a number of metabolic processes including energy homeostasis. Alterations in SNS effects on metabolism have been implicated in the development and maintenance of obesity, and the SNS is a potential therapeutic target in the treatment of obesity. This short review provides an overview of the anatomical and physiological aspects of the SNS, before considering the evidence showing a role for the SNS in the development or treatment of obesity.

### II ORGANIZATION AND STRUCTURE OF THE SNS

The autonomic nervous system consists of the sympathetic nervous system, parasympathetic nervous system (PNS), and adrenal medulla. A number of anatomical differences distinguish the SNS and the parasympathetic nervous system, which are reviewed in detail by Astrup and Macdonald (1). The important struc-

tural aspects of the SNS are that the preganglionic nerves arise from thoracic and lumbar regions of the spinal cord, and that the ganglia are close to the spinal cord. Thus, the SNS has long postganglionic nerves, which innervate almost all of the vital organs and tissues of the body. While most of these vital organs and tissues are also innervated by the parasympathetic nervous system, major exceptions are the blood vessels, sweat glands, and adipose tissue, which have only a sympathetic nerve supply. The adrenal medulla is effectively a sympathetic ganglion, but it releases hormones directly into the bloodstream instead of having a postganglionic nerve. There are many physiological and clinical situations in which activation of the SNS and adrenal medulla are dissociated, and it is more appropriate to consider them as the sympathoadrenal system than to include the adrenal medulla in the SNS. The other distinctive anatomical feature of sympathetic nerves is that they have varicosities along the length of nerve within the tissue that is innervated. Thus, each nerve releases neurotransmitters at a number of sites.

The SNS and PNS nerves, which arise from the spinal cord and supply the vital organs and tissues, represent the efferent part of the autonomic nervous system. Activation of these nerves usually occurs as part of reflex mechanisms that involve afferent signals

and some processing in the central nervous system. Many of the afferent signals involved in these reflexes travel to the brain in afferent nerve fibers located in the sympathetic and parasympathetic nerve trunks. The most important structure for the integration of these afferent signals is the hypothalamus, which also receives inputs from higher brain centers. Thus, the hypothalamus is the major regulator of SNS activity, and is undoubtedly of major importance in the control of metabolism and energy homeostasis. As shown schematically in Figure 1, it is now well established that stimulation of the parasympathetic nervous system is associated with an anabolic effect (stimulation of food intake and inhibition of energy expenditure), whereas stimulation of the SNS is associated with a catabolic state in which food intake is decreased and energy expenditure is increased.

A large number of neurotransmitters and neuromodulators are involved in the central nervous control of the autonomic nervous system (2). The neuromodulators are normally peptides, coreleased with the classical neurotransmitters, and have a variety of effects to alter the response to the neurotransmitter. While the detail of such central control of autonomic (including SNS) efferent activity is beyond the scope of this review, it should be recognized that effects on the central nervous system may affect peripheral functions controlled by the SNS. The principal peripheral neurotransmitters in the autonomic nerves are acetylcholine and noradrenaline

(norepinephrine). In the ganglia (both sympathetic and parasympathetic), the major neurotransmitter is acetylcholine, but a number of neuromodulatory neuropeptides are also present (3). The major postganglionic neurotransmitter in the SNS is noradrenaline (norepinephrine), while parasympathetic nerves almost exclusively release acetylcholine (and some peptides) from the nerve terminals. Some sympathetic nerves (such as those innervating the sweat glands) release acetylcholine rather than noradrenaline, and most sympathetic nerves also release a number of neuropeptides.

The predominant receptors of interest in the postganglionic sympathetic nerves are also those that mediate the effects of noradrenaline, or other catecholamines such as adrenaline (epinephrine). These catecholamine receptors are known as adrenoceptors, which are grouped into  $\alpha$  and  $\beta$  subtypes. There are at least two types of  $\alpha$ -adrenoceptor and three types of  $\beta$ -adrenoceptor.  $\alpha$ -Adrenoceptors are particularly common in blood vessels, with vasoconstriction occurring when the receptors are stimulated by noradrenaline. By contrast, stimulation of  $\beta$ -adrenoceptors usually causes relaxation of vascular or bronchial smooth muscle. A major distinction between  $\alpha$ - and  $\beta$ -adrenoceptors is in their second-messenger mechanisms. Cyclic AMP generation is a key second messenger for most if not all  $\beta$ -adrenoceptor-mediated responses, although the detailed mechanisms are rather complex, and vary between tissues and receptor types, involving G-proteins and other membrane components.  $\alpha$ -Adrenoceptor activation produces different second messengers, mainly through the generation of phosphatidylinositol and diacylglycerol, causing an increase in intracellular calcium and often a decrease in cAMP.

**Figure 1** Schematic representation of the autonomic control of energy balance. Overall, an enhanced activity of the SNS tends to decrease the energy stores by decreasing energy intake and increasing energy expenditure, whereas an impaired activity is associated with increased energy stores and possibly obesity. On the contrary, an enhanced activity of the PNS is associated with obesity, whereas an impaired activity may be associated with leanness.

### III PHYSIOLOGICAL ROLE OF THE SNS

The aspects of SNS function that are of specific interest in relation to metabolism and obesity concern the regulation of the cardiovascular system, gastrointestinal function, pancreatic hormone secretion, and adipose tissue lipolysis. The single most important role of the SNS is the maintenance of an adequate blood pressure to maintain functioning of the vital organs. This is achieved principally by the sympathetic control of cardiac output and blood vessels, although it should be recognized that the parasympathetic innervation of the heart has a part to play. In most tissues or organs, stimulation of the sympathetic nerves produces vasoconstriction, reducing blood flow and potentially rais-

ing blood pressure. However, in some tissues (e.g., adipose tissue, skeletal muscle, and some skin areas) sympathetic activation can produce vasodilatation, increasing blood flow. Nevertheless, in most cases when tissue blood flow increases, it does so either because of effects of local metabolites or because of a reduction in sympathetic vasoconstriction. The importance of the SNS in the control of the cardiovascular system should not be overlooked, as any nonspecific stimulation or antagonism of the SNS intended to produce metabolic effects will also have significant cardiovascular effects that could be undesirable.

SNS activation has a general inhibitory effect on gastrointestinal function, reducing intestinal motility and gastric emptying. This contrasts with its general stimulatory effect on many other physiological processes. The SNS has a major role in the control of

lipolysis in adipose tissue, both directly and due to the effects on pancreatic hormone secretion (1,4). The major metabolic effects of the SNS and plasma adrenaline are summarized in Figure 2.

In most physiological situations, the SNS is activated in a discrete manner, with stimulation of some tissues and no effect on others. This was clearly identified by Muntzel et al. (5), who showed that intracerebroventricular (ICV) administration of insulin to rats activated sympathetic outflow to the hind limbs (mainly skeletal muscle) but not to other areas. It is only in extreme circumstances, e.g., profound hypotension or the “fight or flight” response, that a generalized sympathetic activation may occur. In metabolic situations such as overfeeding, fasting, or hypoglycemia in rats, there is selective activation or inhibition of sympathetic activity in some organs, with no change in others (6). Thus, any

**Figure 2** Summary of the metabolic effect of the sympathetic nervous system (SNS) and plasma adrenaline. Shaded boxes represent plasma compartments for hormones or substrates, solid lines represent effect of adrenaline from the adrenal medulla, and dashed lines represent activities mediated by sympathetic nerves. Other thin lines represent exchanges through the bloodstream.

consideration of the role of altered SNS or adrenal medullary activity in relation to obesity must take account of the discrete manner in which these systems are involved in physiological regulation.

#### IV METHODS FOR ASSESSING SNS ACTIVITY

A number of techniques are routinely used to assess SNS activity, but none of them are able to provide reliable information under all conditions. When assessing SNS activity, three important components must be recognized: the neural reflex arc, the end-organ responsiveness, and the existence of compensatory systems (7). Thus, just to obtain an index of efferent nerve activity, without some assessment of the functional consequences of any change recorded, can be misleading. Moreover, when possible, one should use more than one technique to assess SNS activity in order to obtain a more reliable assessment.

##### A Nerve Activity

The activity of the efferent sympathetic nerves can be determined by direct nerve recording (microneurography). The use of microneurography to assess SNS activity was pioneered by Wallin and colleagues (8). The technique involves the insertion of a fine tungsten microelectrode into a nerve, and is thus restricted to peripheral nerves such as the peroneal nerve in the leg. This technique can only provide information on SNS activity in the skin and skeletal muscle, and measurements can only be made with a subject resting quietly to avoid displacement of the electrode. The technique has been used to investigate the control of the cardiovascular system, and it is now clear that muscle sympathetic nerve activity (MSNA) is mainly related to the control of blood pressure, and that an increase in nerve firing rate is usually associated with vasoconstriction in skeletal muscle. However, this is not always the case, as there are a number of situations in which vasodilatation occurs despite an increase in muscle sympathetic nerve activity (1).

Thus, assessing peripheral sympathetic nerve firing rate in humans provides an index of the SNS supplying skeletal muscle, but in some circumstances this may not reflect overall sympathetic activity in the whole body. This is illustrated by the studies of sympathetic activity in obesity, where the measurement of plasma or urinary catecholamines in obese and non-obese subjects shows no clear consensus as to whether

the obese have altered sympathetic activity. However, the few studies of muscle sympathetic nerve activity in lean and obese subjects consistently report increased activity in the obese. Thus, depending on how sympathetic activity is assessed, one would conclude the obese have either normal or elevated SNS activity (9).

##### B Neurotransmitter Release

It is very difficult to determine the rate of release of neurotransmitters from efferent sympathetic nerves, as the released molecules can undergo a number of different metabolic fates, including reuptake into the neuron, metabolism in the synaptic cleft, uptake into surrounding tissues, or spillover into the plasma. This last has been used as an index of SNS activity and can be obtained from radioactive tracer-based measurements of noradrenaline (10) or of urinary noradrenaline excretion (11). The use of arterial blood samples in the spillover technique allows an assessment of whole-body SNS activity, while regional venous blood sampling will allow SNS activity to be determined in a variety of tissues (12). By contrast, urinary excretion of noradrenaline provides information on the whole body, integrated over the period of the urine collection. The use of either the spillover technique or urinary noradrenaline excretion to assess the SNS relies on a constant relationship between release, spillover, and metabolism of noradrenaline. Any condition, or drug, that alters this relationship (e.g., a neuronal noradrenaline re-uptake inhibitor) could invalidate the index of SNS activity.

Plasma noradrenaline concentration per se provides limited information on SNS activity, as noradrenaline in the plasma arises from spillover from sympathetic nerves and release from the adrenal medulla. Thus, alteration in plasma noradrenaline could be the result of changes in adrenal medullary activity, although in most situations changes in SNS activity are responsible for alterations in plasma noradrenaline. If plasma noradrenaline is to be used to assess whole body SNS activity, it is more appropriate to use arterial [reviewed by Hjendahl (13)] or arterialized venous blood samples (14) to avoid the errors produced by uptake and release of noradrenaline by forearm tissues.

In principle, the use of plasma adrenaline concentrations to assess adrenal medullary activity is more straightforward, although changes in clearance of the catecholamine from plasma can produce errors. For example, the nonselective  $\beta$ -adrenoceptor antagonist propranolol reduces the clearance of catecholamines from plasma and produces higher plasma concentra-

tions of noradrenaline and adrenaline for a given rate of release or spillover (15).

## V FACTORS AFFECTING SNS ACTIVITY OR RESPONSIVENESS

A variety of metabolic factors can alter the activity of the SNS or change the response to adrenoceptor activation. The classical studies of Landsberg and Young (6) showed that underfeeding of rodents led to a decrease in SNS activity, especially to the heart and brown adipose tissue, whereas overfeeding had the opposite effect. While similar effects of underfeeding on the SNS may occur in humans, starvation for up to 4 days does not reduce the lipolytic and thermogenic responses to infused catecholamines [reviewed by Macdonald and Webber (16)]. It has been argued that this reduced SNS activity during underfeeding is of survival value in reducing resting energy expenditure and thus prolonging survival. Such a mechanism would then explain possible links between reduced SNS activity and the development or maintenance of obesity discussed below.

As mentioned earlier, administration of insulin into the brain in rats increases muscle SNS activity (4), and similar effects are seen in humans when insulin is infused intravenously (i.e., muscle sympathetic nerve activity and plasma noradrenaline both increase) (17). It has long been established in clinical situations that there is a synergy between catecholamine and thyroid hormone effects on the cardiovascular system and metabolism. In situations of less severe disturbances of thyroid function, mild hyperthyroidism can increase metabolic rate and cardiac responses to administered catecholamines (18), while mild hypothyroidism reduces baseline heart rate and metabolic rate but does not affect the response to catecholamines (19).

There has been major interest in recent years in the possibility that receptor polymorphisms may be associated with altered function and have an etiological role in the development of disease. In the area of obesity, attention has been focused on the association of adrenoceptor (in particular the  $\beta_2$  and  $\beta_3$  adrenoceptors) or uncoupling protein (UCP1) polymorphisms, and the obese state. Most studies have failed to show convincing associations between obesity and receptor polymorphisms, although Large et al. (20) did show that a sevenfold increased relative risk of obesity was associated with a  $\beta_2$ -adrenoceptor polymorphism (Glu27 homozygosity). Interestingly, this polymorphism was not associated with any altered function of the  $\beta_2$ -

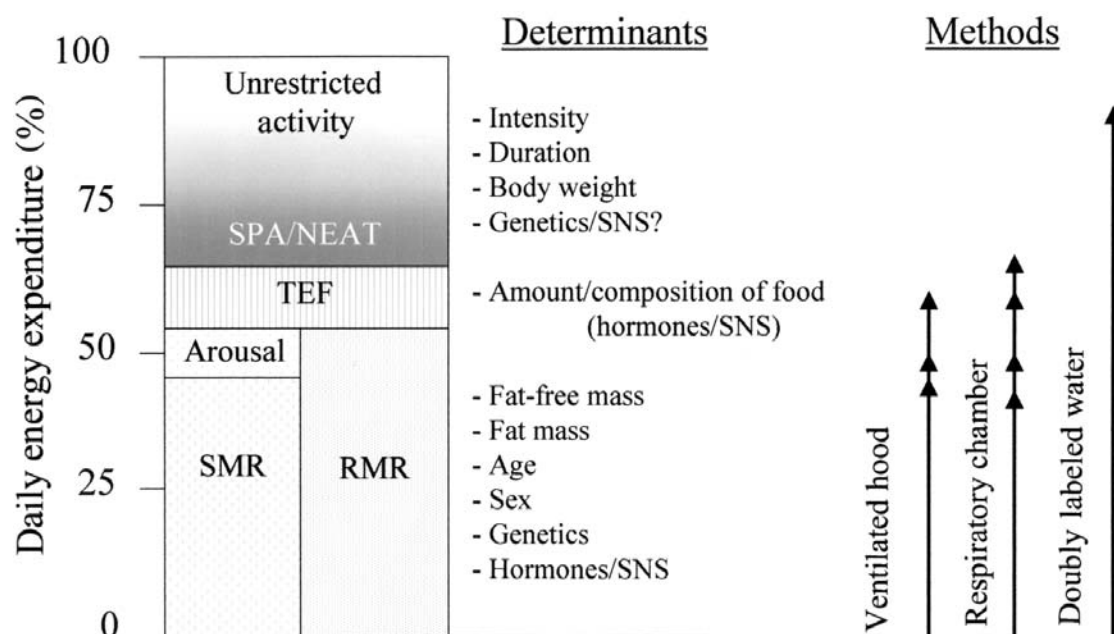

adrenoceptor, while a different receptor polymorphism (Arg16Gly) was accompanied by increased receptor sensitivity in adipose tissue. More recently, Valve et al. (21) showed that combined polymorphisms of the  $\beta_3$ -adrenoceptor and UCP1 were associated with a low resting metabolic rate in obese Finns. However, many genetic association studies have failed to reproduce this finding (22). Taken together, these studies indicate a need to consider alterations in responsiveness to SNS activation or adrenal medullary hormone secretion as possible contributory factors to the development of obesity in humans.

## VI ROLE OF LOW ENERGY EXPENDITURE IN THE PATHOGENESIS OF OBESITY

The daily energy expenditure (EE) of an individual can be divided into its components as illustrated in Figure 3. The resting metabolic rate (RMR) comprises 50–80% of the total daily EE and varies greatly among individuals. About 70–80% of this variance can be accounted for by differences in fat-free mass, fat mass, age, and gender (23). After accounting for these variables, studies in Pima Indians have indicated that an additional 7–11% of the variance in RMR is accounted for by family membership, strongly suggesting that RMR is influenced by genetic factors (24). Several studies support the idea that a low RMR is associated with weight gain. A low metabolic rate has been shown to precede body weight gain in infants (25), children (26), and adults (27). Based on the assumption that formerly obese, weight-reduced subjects exhibit the metabolic characteristics that predisposed them to obesity, several studies have compared metabolic rates in formerly obese subjects to those of weight-matched controls who have never been obese. A meta-analysis of 12 such studies corroborates the prospective data by demonstrating a 3–5% lower mean RMR in the formerly obese subjects (28). Moreover, these data indicate that a low RMR is more frequent among formerly obese subjects than among “never-obese” control subjects.

The thermic effect of food (TEF) is commonly defined as the increase in EE in response to food intake. Although TEF accounts for only ~10% of daily EE, many researchers believe that a low TEF plays a role in the development of obesity. Some data supporting this view have been presented, but the issue is still debated (29,30). Importantly, in the only prospective study to date, a low TEF was not associated with weight gain (31).

**Figure 3** Components of daily energy expenditure, their major determinants and the methods by which they can be measured. SPA, spontaneous physical activity; NEAT, nonexercise activity thermogenesis; SMR, sleeping metabolic rate; RMR, resting metabolic rate; SNS, sympathetic nervous system.

When confined to a respiratory chamber, individuals differ as to how much they move around spontaneously, change position, and fidget. This *spontaneous physical activity* can be measured (23), and a low spontaneous physical activity is a risk factor for body weight gain in men (32). Recently, Levine et al. (33) showed that subjects who did unconsciously increase their spontaneous physical activity in response to overfeeding were resistant to weight gain compared to those who did not. They coined the term NEAT, for this “Non-Exercise Activity Thermogenesis” component of energy expenditure.

During indirect calorimetry measurements, the contributions of carbohydrate, lipid, and protein to total EE can be determined. The respiratory quotient (RQ) is calculated as the molar amount of  $\text{CO}_2$  produced, divided by the amount of  $\text{O}_2$  consumed, with a value of 1.0 indicating that glucose is the sole metabolic substrate, whereas a value of 0.71 indicates that fat is the fuel source. A high RQ (i.e., closer to 1.0 than 0.71) indicates a high oxidation of carbohydrate relative to lipid. Evidence that a high RQ predisposes to weight gain has been obtained in prospective studies (34,35) as well as in studies in formerly obese subjects (36–39). Therefore, both impaired energy expenditure and impaired fat oxidation can predispose individuals to

weight gain. We here briefly discuss how the sympathetic nervous system can influence the different metabolic predictors of weight gain.

## VII CONTRIBUTION OF THE SNS TO EE AND ITS COMPONENTS

### A Energy Expenditure (24-hr EE and RMR)

Observations in rats indicate that the SNS stimulates thermogenesis and that dietary manipulation influences noradrenaline turnover. These findings have promoted interest in the role of the SNS in body weight regulation in humans. During short-term studies, sympathomimetic agents clearly increase EE (40). In a long-term, crossover study in seven white males, 24-hr EE tended to be lower during administration of the  $\beta$ -antagonist propranolol than placebo or the  $\beta_2$ -adrenergic agonist terbutaline (41). However, lipid oxidation was increased by terbutaline (41). In another study (42), 24-hr EE measured in a respiratory chamber was positively correlated with urinary noradrenaline excretion. Furthermore, administration of the  $\beta$ -antagonist propranolol caused a 4% decrease in RMR in white people but, interestingly, not in Pima

Indians (42), suggesting a dissociation of SNS and RMR in Pima Indians, a population with one of the highest prevalence rates of obesity in the world. In yet another study (43), adjusted 24-hr EE, sleeping metabolic rate, and RMR were correlated with MSNA in white people, but again, there was no relationship in Pima Indians. Noradrenaline turnover studies have shown that most of the variability in RMR unexplained by body size and composition is related to differences in SNS activity (44,45). Taken together, the above studies suggest that SNS activity does modulate RMR, the largest component of daily EE.

### B Thermic Effect of Food

Studies in which  $\beta$ -blockade is used have demonstrated a facultative,  $\beta$ -adrenergically mediated component of glucose-induced thermogenesis. Furthermore, it has been shown, by measurement of plasma noradrenaline turnover (46,47), that the increased SNS activity in response to a meal accounts for at least part of the meal-induced TEF. The major drive for the increase in SNS activity in response to a meal seems to be insulin (48). Despite the clear impact of SNS activity on TEF, the contribution of TEF to total EE may be too small to have an impact on body weight gain, as suggested by prospective data (31).

### C Spontaneous Physical Activity or NEAT

The relationship between spontaneous physical activity and noradrenaline appearance rate (49) is consistent with the idea that SNS activity is a determinant of how much subjects move around, change position, and fidget, all of which contribute to total EE. In other words, "fidgeters" seem to have higher activity of the SNS. It remains to be determined, however, whether the increased SNS activity in those who fidgets is a contributing factor to the fidgeting, or secondary to the increased activity associated with fidgeting. The mechanisms underlying the variability in the induction of NEAT in response to overfeeding are unknown, and it will be interesting to test the impact of the activity of the autonomic system on this variability. Recent data from the NIH group in Phoenix showed that spontaneous physical activity measured in a respiratory chamber is related to the level of physical activity in free-living conditions (50). Taken together, the results suggest that a higher sympathetic tone may drive an increase in both spontaneous physical activity and habitual physical activity, therefore protecting individuals against body weight gain.

### D Substrate Oxidation

The effects of the SNS on metabolism appear to influence the relative amounts of substrate oxidized (41). Accordingly, an inverse relationship was demonstrated in white people between 24-hr RQ (measured in a respiratory chamber) and basal muscle sympathetic nerve activity (measured immediately after the stay in the respiratory chamber) (51). The relationship between RQ and SNS activity was independent of the percentage of body fat and clearly indicates an association between a low SNS activity and a low lipid oxidation. A possible explanation for this observation is the stimulatory effect of noradrenaline on intracellular lipolysis and on free fatty acids uptake in the muscle, which seem impaired in previously obese subjects (52).

### E Responsiveness to Sympathetic Stimuli

Decreased *responsiveness* to sympathetic stimuli may be as equally important as decreased *activity* of the SNS for the development of obesity. Defects of catecholamine-induced lipolysis have been observed in a number of obese subjects, but polymorphisms of the  $\beta_2$ -(20) and  $\beta_3$ -receptors (53) were proposed as explanations for the impaired lipolysis. Using an in vivo model for studies of neural control of adipose tissue lipolysis (intraneural electrical stimulation of the lateral cutaneous femoral nerve), Dodt et al. (54) showed that human obesity is characterized by a profound unresponsiveness of the subcutaneous adipose tissue to lipolysis. Decreased responsiveness could possibly be caused by polymorphisms in the genes encoding the various types of adrenoceptors, but may also be due to a reduced number of those receptors in the obese. A variant in the gene encoding for the  $\beta_3$ -adrenoceptor, resulting in the substitution of tryptophan with arginine in position 64 (trp64arg) of the receptor protein, has been associated with obesity and diabetes in some studies (55), and exhibits impaired signaling when expressed in Chinese hamster ovary (CHO) cells under certain, but not all, experimental conditions (56,57). A number of genetic polymorphisms in the  $\beta_2$ -adrenoceptor have also been reported (20), some of which are associated with functional abnormalities, and some of which are associated with obesity, but none of which are associated with both (20). At the intracellular level, cAMP released owing to SNS stimulation may affect the expression and the thermogenic function of the uncoupling proteins (UCPs). Lately, attention has been focused on UCP3, which is mostly expressed

in muscle. UCP3 mRNA expression increases in response to overfeeding and fasting (probably through increased availability of NEFAs) and in response to adrenergic stimulation. The UCP3 and UCP2 genes are located adjacent to each other in a region implicated in linkage studies as contributing to obesity (58), and a polymorphism in the gene encoding for UCP3 has been associated with reduced fat oxidation (59). However, the potential uncoupling activity of UCP2 and UCP3 is still debated (60) despite the fact that massive overexpression of human UCP3 in mice was associated with increased metabolic rate (61).

### VIII LOW SNS ACTIVITY IS ASSOCIATED WITH WEIGHT GAIN

In rodents, administration of the adipocyte hormone leptin promotes negative energy balance, the latter partly mediated by increased SNS outflow to a number of organs including brown adipose tissue. Accordingly, animals with defective leptin biosynthesis or receptor function (e.g., the *ob/ob* mouse, the *db/db* mouse, or the *fa/fa* rat) have markedly reduced SNS activity and become obese. Rodents made obese by lesions of the ventromedial hypothalamus have a reduced firing rate of sympathetic nerves to the brown adipose tissue in the basal state and in response to dietary and environmental stimuli. This reduced SNS activity is associated with low metabolic rate and hyperphagia (62). Studies in humans in whom SNS activity or adrenal medullary function is compared between lean and obese subjects have yielded very conflicting results, as reviewed (63), probably because comparisons of lean and obese subjects provide only very limited information about the role of the SNS in the etiology of obesity as they do not discern between causes and consequences of weight gain. A better approach is to establish the relationship between SNS activity and subsequent weight gain. The only such report we are aware of (64) demonstrates a relationship between low urinary noradrenaline excretion and weight gain, and a relationship between low urinary adrenaline excretion and the development of central obesity. These results strongly suggest that a low SNS activity is also a risk factor for weight gain in humans. SNS activity increases in response to weight gain, thereby attenuating the original impairment. It is of interest to note that basal MSNA for a given percentage of body fat is lower in Pima Indians compared to white people (41,43), possibly contributing to the propensity to obesity in the Pima Indians.

### IX SNS ACTIVITY AS A PREDICTOR OF WEIGHT LOSS DURING TREATMENT OF OBESITY

Because sympathetic activity is an important determinant of EE and plays a role in the propensity to weight gain in some individuals, it is likely that constitutional differences in SNS activity may contribute to explain the large variability in weight loss among obese individuals on dietary treatment programs. Sympathetic activation has also been associated with enhanced meal-induced satiety (65), which suggests that the SNS exerts a dual effect, i.e., working on both sides of the energy balance equation. Pharmacological blockade of the SNS is difficult to achieve, but a certain functional inhibition occurs during chronic treatment with a number of agents, such as  $\beta$ -adrenergic antagonists (1). Treatment of hypertensive or other patients with  $\beta$ -antagonist produces an average of 2- to 5-kg weight increase, which can be entirely accounted for by fat gain (66). Even if other unknown regulatory mechanisms may counteract further weight gain (67), it is interesting that some individuals experience a rather large weight gain during inhibition of their SNS.

The habitual SNS activity may also play a role in variability in weight loss during the treatment of obese patients. Three studies have assessed the relationship between pretreatment SNS activity of obese subjects and weight loss outcome during hypoenergetic dieting. In a study of obese females who underwent 36 weeks of 4.2-MJ d<sup>-1</sup> diet, pretreatment levels of postprandial plasma noradrenaline were positively associated with the maximum achieved weight loss, and a low plasma noradrenaline level was found to be a risk factor for a small weight loss (68). Similarly, pretreatment levels of both plasma noradrenaline and adrenaline were found to be positively associated with fat loss in 63 obese patients undergoing an 8-week, very low energy diet (2.8 MJ d<sup>-1</sup>) (69). In a third study, Hellström et al. (70) found that plasma noradrenaline and  $\alpha_2$ -adrenoceptor sensitivity was associated with fat loss during 4 weeks on a 1.6-MJ d<sup>-1</sup> diet. These studies suggest that obese patients with low SNS activity are less responsive to diet-induced weight loss programs and that plasma noradrenaline can be used as a prognostic marker of weight loss.

### X DIETARY STIMULATION OF SNS

It is not entirely clear from the literature if basal metabolic rate (BMR) and 24hr EE can be influenced

by the dietary macronutrient composition. However, there are some studies indicating that the carbohydrate content of the diet may slightly increase EE. Toth and Poehlman (45) studied the diet composition and RMR of vegetarians and nonvegetarians. Vegetarians reported a greater intake of carbohydrates than non-vegetarians (62% vs. 51%), whereas no difference was found in body composition or aerobic capacity. Vegetarians had an 11% higher RMR, which could be explained by their higher SNS activity due to the higher carbohydrate intake (45). Some, but not all, intervention studies also support that a high-carbohydrate diet increases EE. One group found that, despite a weight loss during 20 weeks on an ad libitum low-fat, high-carbohydrate diet, energy intake was 19% higher than a control group consuming a high-fat diet (71). An analysis of physical activity level could not identify any change in daily activity level, which suggests that other components of EE were affected (72). Strictly controlled dietary intervention studies have demonstrated that EE is increased only by high-carbohydrate diets with high contents of simple sugars. Vasilaras et al. (73) compared the impact of high-sucrose versus high-starch diet on 24-hr EE and SNS activity. After 14 days on the sucrose diet, 24-hr EE, as well as postprandial plasma adrenaline and noradrenaline concentrations, was significantly higher than on the high-starch diet and on a high-fat control diet. The results have been confirmed by the European multicenter randomized trial CARMEN, in which about 300 overweight and obese subjects completed 6 months ad libitum intake of low-fat diets, rich in either simple or complex carbohydrates (74). Only the diet rich in simple carbohydrates increased EE, whereas no effect was seen with the complex carbohydrates. The reason for the differences between the carbohydrates is probably to be found in the effect of fructose on EE and SNS activity. Several studies have found that fructose and sucrose increase EE after intake, compared with glucose and starch (74,75). However, this advantage of simple over complex carbohydrates should be balanced against the reverse effects on satiety and energy intake.

## Energy Expenditure and Substrate Oxidation

**Jean-Pierre Flatt**

University of Massachusetts Medical School, Worcester, Massachusetts, U.S.A.

**Angelo Tremblay**

Laval University, Sainte-Foy, Quebec, Canada

### I FACTORS DETERMINING TOTAL SUBSTRATE OXIDATION

The rate of substrate oxidation varies considerably during the day, being dictated by the body's need to regenerate the adenosine triphosphate (ATP) used in carrying out its metabolic functions, in digesting and storing nutrients, in moving, and in performing physical tasks. The amount of heat generated is generally sufficient to allow maintenance of body temperature by regulation of heat dissipation, aided when necessary by measures seeking to maintain comfort through appropriate clothing and control of environmental temperatures. Situations where substrate oxidation is activated for the sake of thermogenesis are avoided as much as possible.

The energy expended in the resting state depends primarily on the size of the lean body mass, plus the metabolic costs for processing ingested nutrients. The energy expended for specific physical activities is highly reproducible and in many cases roughly proportional to body weight (1). Overall energy expenditure for weight maintaining adults is thus determined primarily by body size and by the intensity and duration of the physical activities undertaken. In sedentary individuals total daily energy expenditure (TEE) varies typically between 1.3 and 1.5 times the

rate of resting energy expenditure (REE) extrapolated to 24 hr.

### A Efficiency of Oxidative Phosphorylation and P:O Ratio

It is difficult to assess the efficiency of oxidative phosphorylation and the P:O ratio in intact cells, because the ATP turnover due to the cell's metabolic activities is not readily measurable. Pahud et al. (2) were nevertheless able to assess the efficiency of oxidative phosphorylation in man by combining direct and indirect calorimetry measurements in young men pedaling on a bicycle ergometer at different levels of work output. During sustained aerobic work, the mechanical work performed was equivalent to 27% of the energy contained in the increment in substrate oxidation elicited by pedaling. During the first minutes of pedaling against a suddenly increased resistance, the mechanical work produced (measured electrically with the bicycle ergometer) plus the energy appearing in the form of heat (measured by direct calorimetry and from the increase in the subjects' body temperature) exceeded the energy liberated by substrate oxidation (determined by indirect calorimetry). This implies that preformed high-energy bonds (ATP and creatine-phosphate) were utilized to accomplish part of the mechanical work during this

phase of the test. The characteristics of this latter process allowed them to determine that the *coupling coefficient*, which describes the efficiency with which chemical energy can be converted into work in muscles, is 41%. The difference in the two observed efficiencies is due to the fact that a fraction only of the energy liberated by the oxidation of metabolic fuels is recovered in the form of ATP. The ratio  $27\%/41\% = 0.66$  thus provides an estimate of the efficiency with which the energy liberated by substrate oxidation is recovered in the form of ATP in human muscles.

During the complete oxidation of 1 mol of glucose,  $\sim 689$  ( $\Delta G$ , kcal/mol)  $\times 0.66 = 450$  kcal of free energy is therefore recovered in the form of high-energy bonds. Since the  $\Delta G$  for ATP hydrolysis in muscle is  $\sim -14.3$  kcal/mol and oxidative phosphorylation operates at near equilibrium conditions, one would expect  $450/14.3 = 31.5$  mol ATP to be formed, which corresponds to a P:O ratio of  $31.5/12 = 2.6$  (3). This is in reasonably good agreement with other evaluations of the P:O ratio in intact cells (3). In reality, such experiments provide evaluations of the increments in ATP generation divided by the increments in oxygen consumption, i.e.,

a “ $\Delta P:\Delta O$  ratio.” This is higher than the P:O ratio prevailing in resting cells, in which the P:O ratio is lower due to a certain rate of proton leakage through the mitochondrial membrane (4), which may account for 20% of resting energy expenditure (5). While ATP turnover based on estimates of the  $\Delta P:\Delta O$  ratio will thus be overestimated, this uncertainty is of lesser importance when increments in ATP turnover are to be assessed. Considering the number of assumptions and sources of possible errors inherent in these estimates, a value of 2.6 still seems to be compatible with the “traditional” values of three and two high-energy bonds regenerated per mitochondrial NADH and per FADH<sub>2</sub> or cytoplasmic NADH reoxidized, respectively. In order to maintain consistency with common practices, these values were used in computing the amounts of ATP yielded by the oxidation of metabolic fuels (Table 1) (6,7) and in the assessment of the metabolic costs of processes based on their ATP-related stoichiometries (Fig. 1) (6).

Extramitochondrial reactions with oxygen are catalyzed by peroxidases, and for diverse hydroxylations catalyzed by oxygenases (where the ultimate reaction

Source: Ref. 6.

**Figure 1** ATP yields during oxidation of carbohydrate, fat, and protein. The numbers printed in brackets show moles of substrate flowing through various metabolic pathways, and, in parenthesis, the moles of ATP produced and expended per mole substrate metabolized, assuming a P:O ratio of 3 for the reoxidation of mitochondrial NADH. (From Ref. 6.)

with oxygen is often catalyzed by the cytoplasmic cytochrome P450), but they account for only 10% of resting O<sub>2</sub> consumption (5). Reactions of the H generated during substrate degradation with oxygen are primarily mediated by cytochrome oxidase, the ultimate enzyme in the mitochondrial respiratory chain, which carries out oxidative phosphorylation. This explains why substrate oxidation *in vivo* is closely controlled by the rate of ADP formation (i.e., the rate of ATP utilization) under most circumstances, except in brown adipose tissue (BAT). BAT mitochondria contain an uncoupling protein (UCP). In the presence of fatty acids produced by catecholamine-stimulated lipolysis (8) this protein creates a proton-conducting pathway which allows NADH reoxidation to occur at rates much higher than those determined when proton reentry is coupled to ATP regeneration. This permits rapid substrate oxidation and heat production, important for the maintenance of body temperature in small animals exposed to cold, as well as in raising body temperature

during arousal from hibernation. Activation of this proton conductance pathway during overfeeding can play an important role in enhancing energy dissipation, thereby limiting fat accumulation during overfeeding in small animals (9,10). This mechanism for energy dissipation does not appear to operate to a significant extent in man (8,11).

## B Costs Associated with ATP Generation

The number of mol of ATP formed per mol glucose, fatty acid, and amino acid oxidized are shown in Table 1, as well as the number of ATP required to initiate their degradation (negative numbers), and in the case of amino acid oxidation to carry out gluconeogenesis and ureagenesis. In order to evaluate the costs of ATP expenditures associated with these and other metabolic processes, the amount of substrate which needs to be oxidized to regenerate a given amount of ATP must be assessed. Such evaluations depend therefore not only

on the P:O ratio, but also on the amounts of ATP expended for the transport, activation, and handling of the metabolic fuels whose oxidation provides the energy for ATP regeneration.

### 1 Substrate Handling and Storage Costs

In the case of glucose, 38 ATPs are produced during the oxidation of one glucose molecule, but two are used for its activation to glucose-6-P and fructose-di-P, so that the ATP yield is  $36/38 = 95\%$ . If one allows for the fact that some 15–25% of the glucose released by the liver is recycled via the *Cori cycle* and the *glucose-alanine cycle* (at a net cost of 4 ATP/glucose recycled), only some 90% of the ATP generated by oxidation of glucose derived from liver glycogen are available to replace ATPs used in peripheral tissues. Significant portions of the carbohydrates supplied by the diet are initially stored in the form of muscle glycogen (12), so that a substantial part of the glucose released by the liver is in fact regenerated from lactate released by breakdown of muscle glycogen. The cost of gluconeogenesis would then consume additional ATP. Assuming that this applies to half of the glucose released by the liver, the net ATP yield during glycogen oxidation is reduced to  $\sim 82\%$  (Fig. 1). The heat of combustion ( $\Delta H$ ) for glucose is 670 kcal/mol (13). Note that the  $\Delta H$  is very similar to the  $\Delta G$  for this process, i.e.,  $-689$  kcal/mol, which is generally the case when complete oxidation of biological substrates are considered. The  $\Delta H$  for fructose-1,6-di-P oxidation may be estimated at 685 kcal/mol. The release of 685 kcal, then reflects the turnover of 38 mol of ATP or  $685/38 = 18$  kcal/mol ATP when glucose is the metabolic fuel oxidized. However, since 18% of the ATP generated merely replaces the ATP spent for substrate handling, an amount of glucose containing  $18/0.82 = 22$  kcal must be oxidized to replace 1 mol of ATP consumed by a given metabolic process.

To evaluate the energy expended in regenerating ATP by oxidation of fat, one has to consider that some of the free fatty acids (FFA) produced by triglyceride hydrolysis in adipose tissue are reesterified before leaving adipose tissue, at a cost of 7 ATP/triglyceride reconstituted. Some of the FFA released into the circulation are removed and reesterified by the liver, to be reexported in the form of lipoproteins, requiring twice 2.33 ATP/FFA (Fig. 1) (6). The extent to which the lipolytic rate exceeds the rate of fatty acid oxidation appears to be rather variable (14). If one assumes that lipolysis proceeds at twice the rate of fat oxidation and that half of

the fatty acids that escape oxidation are reesterified in adipose tissue while the other half are returned to adipose tissue via lipoproteins secreted by the liver, 3.5 ATP is expended per mol fatty acid oxidized.

Oleate is the most common fatty acid in human triglycerides. During its oxidation 146 ATP/mol are generated, while 2 ATP are expended for its activation to oleyl-CoA. The ATP yield for fat oxidation is thus  $\sim 140.5/146 = 96\%$ . In view of the large amount of ATP generated per mol fatty acid oxidized, some variations in the relative rate of FFA reesterification will not greatly modify this yield. The  $\Delta H$  for oleate oxidation is 2657 kcal/mol (13), and that for oleyl-CoA can be estimated at 2670 kcal/mol, so that  $2670/146 = 18.3$  kcal are released per mole ATP turned over. The energy expenditure per mole of ATP utilized and replaced by fatty acid oxidation thus comes to  $18.3/0.96 = 19$  kcal/mol ATP (as compared to 22 kcal/mol ATP during glycogen oxidation) (Fig. 1).

By taking into account the known heats of combustion and the amino acid content of various proteins, Livesey and Elia (15) concluded that the RQ during protein oxidation is 0.835, and that 4.7 kcal is released per gram protein metabolized to  $\text{CO}_2$ , water, and urea, rather than 0.80 and 4.32, respectively, which were generally used (15). With protein, 110 g represents an assembly of 1000 mmol of various amino acids (Table 1). In the course of the oxidation of 1 mol of protein,  $110 \text{ g} \times 4.70 \text{ kcal/g} = 517$  kcal and 28.8 mol of ATP are generated (16), or  $517/28.8 = 18$  kcal/mol ATP. (With the old coefficients, the corresponding value would be 16.5 kcal/mol ATP generated, which is not consistent with the values of 18.0 to 18.3 kcal/mol ATP generated during carbohydrate and fat oxidation.) Since the costs of gluconeogenesis and ureagenesis consume 5.5 mol ATP/1000 mmol mixed AA oxidized, or  $\sim 20\%$  of the amount generated (Table 1), the oxidation of  $18/0.8 = 22$  kcal of protein is required to generate 1 mol of ATP.

Only some of the amino acids produced by protein breakdown are oxidized (possibly about 1/3) (17), so oxidation of amino acids derived from endogenous protein turnover is always accompanied by protein resynthesis, a process requiring  $\sim 5$  ATP/amino acid reincorporated into protein (i.e., four for the synthesis of the peptide bond plus an estimated 1 additional mol for amino acid transport, mRNA synthesis, etc.). This would consume 10 ATP in addition to the 5.5 utilized for glucose and urea synthesis per mol amino acid oxidized. The net ATP yield associated with the oxidation of amino acids derived from the turnover of en-

ogenous proteins would accordingly be in the order of  $(28.8-15.5)/28.8 = 46\%$ . When amino acids contribute either 15% or 20% of the fuel mix oxidized, assuming commensurate differences in protein turnover rates would predict a 3% difference in metabolic rates. Part of the variability in basal metabolic rates is indeed explained by differences in protein turnover (18). Furthermore it is well known that elevations in urinary nitrogen excretion and in resting metabolic rates run a parallel course following trauma or during sepsis (19).

The ATP yielded by different nutrients is further decreased when one takes into account the costs incurred for their initial transport and storage after ingestion. Assuming that in addition to the 2 ATP used for the synthesis of glycogen, 0.5 ATP is expended for active transport and intestinal enzyme synthesis and motility, this would entail an energy expenditure equivalent to  $2.5 \times (22.5 \text{ kcal per mol ATP replaced at a postprandial RQ of } 0.89) = 56 \text{ kcal}$ , or  $56/670 = 8\%$  for the storage of dietary carbohydrate as glycogen. That some of the ingested glucose is used without prior conversion into glycogen (assumed to be 20% in Fig. 1) is approximately offset by the stimulation of the sympathetic nervous system induced by carbohydrate intake (20). In studies in which the amount of glycogen synthesis could be calculated from indirect calorimetry data, the predicted energy expended for glucose storage amounted to 4–6% of the glucose energy infused, and accounted for about two-thirds of the observed increase in energy expenditure above the fasting rate, the remainder being attributable primarily to increased catecholamine secretion (20).

When the catecholamine effect is curtailed by administration of adrenergic blocking agents, the thermic effect observed is consistent with the predicted metabolic expense for glucose storage. Taking into account the energy dissipated during the postprandial phase, the net ATP yield from dietary carbohydrate comes to  $\sim 0.92 \times 82\%$  (the net ATP yield for glycogen oxidation) = 75%. In the case of fat, the predictable cost for the initial deposition of dietary fat comes to about 3% of the energy provided by dietary fat, though addition of fat generally appears to raise postprandial energy expenditure by 5–10% of the energy provided by the added fat (21). The net ATP yield from dietary fat would thus be reduced to about  $0.93\% \times 96\%$  (the yield from endogenous fat), or some 90%. These considerations suggest that the oxidation of  $18/0.75 = 24$  kcal of dietary carbohydrate, or the oxidation of  $18.3/0.90 = 20.3$  kcal of dietary fat is needed to replace 1 mol of ATP, or that some 15–20% more energy may be re-

quired to sustain metabolism with dietary carbohydrate than with dietary fat, even in the absence of lipogenesis.

## 2 Diet Composition and Energy Expenditure

In animal studies, Donato and Hegsted (22) reported that 35% of the energy consumed in excess of maintenance requirements was retained when the excess was provided in the form of fat, as compared to 28% when the excess was carbohydrate. In mice whose 24-hr energy expenditure was measured individually for many consecutive days, the use of carbohydrate as a fuel, as compared to fat, was accompanied by 9–12% higher rates of energy expenditure (6). Hurni et al. (23) found sleeping metabolic rates, basal metabolic rates (BMRs), and 24-hr energy expenditure to be 5–8% higher in a group of volunteers when they were consuming a high-carbohydrate diet (80% of energy as CHO, 5% as fat), as compared to a mixed diet (55% CHO, 30% fat). On the other hand, Abbott et al. (24) could find no difference in 24-hr expenditure among obese Pima Indians adapted to diets providing 42% fat and 43% carbohydrate, or 20% fat and 65% carbohydrate. However, in many studies in which total daily energy expenditure was measured while the proportions of CHO and fat in the diet differed substantially, slightly higher energy expenditures on high-carbohydrate than on high-fat diets have been observed, though the differences were not statistically significant (25,26,27). Since a 15% difference in net ATP yields, applied to the proportion of carbohydrate exchanged for fat, would only lead to a relatively minor difference in overall expenditure, this effect remains uncertain, though it can be concluded that its practical impact is negligible.

The increase in resting energy expenditure, i.e., the *thermic effect of food* (TEF) (cf. Chap. 25), elicited by protein consumption varies between 20% and 30% (28,29). The ATP required to absorb and transport dietary amino acids into cells, and then to convert them into protein, may be estimated at  $\sim 5.5$  mol ATP/mol mixed amino acids. If the amino acids are oxidized instead, the ATP expenditure for transport, ureagenesis, and gluconeogenesis also comes to  $\sim 5.5$  mol ATP (16,30). The TEF of protein is therefore essentially the same when either (or any combination) of these two processes is involved:  $(5.5 \times 22.5 \text{ kcal/ATP replaced}) / (110 \text{ g} \times 4.70 \text{ kcal/g}) = 25\%$  (31). However, depending on the proportion of amino acids initially converted into protein, subsequent costs for protein turnover will vary, until an amount of amino acids equivalent to that

initially incorporated into protein has in turn been degraded and converted into glucose and urea. Protein intake can thus be expected to influence energy expenditure beyond the postprandial phase. For instance, in patients receiving fixed amounts of energy by intravenous infusion, but in whom 0.31 g of dextrose/kg body weight (BW)/d was replaced by an equicaloric amount of amino acids (to provide 364 instead of 180 mg of amino acid nitrogen/kg BW/d), an increase in energy expenditure of 2.2 kcal/kg/d was observed (32). This is equivalent to 40% of the energy content of the additional dose of amino acids. Considering that the amino acids were provided intravenously, and that there was a concomitant decrease in metabolic costs for handling glucose, one would expect dietary protein to raise the metabolic rate by an amount approaching half of its energy content.

Based on the “best guesses” described above, the ATP expended for substrate handling (transport, storage, recycling, and activation) dissipates ~10%, 25%, or 45% of the ATP produced in the metabolic degradation of dietary fat, carbohydrate and protein, respectively. The *net ATP yields* are thus estimated to decline from 90% with fat, to 75% with carbohydrate, to 45% with protein. On this basis, a change in protein intake from 75 to 100 g/d would be expected to increase energy expenditure by ~50 kcal/d. Depending on the composition of the diet consumed and the time elapsed after food intake, the cost for replacing one mol of ATP would be expected to vary between 20 and 22 kcal. This is some 10–20% more than the 18 kcal released per mol ATP turned over.

### 3 Cost for Glucose Conversion to Fat

Several reactions in the fatty acid-synthesizing pathway require ATP, so conversion of glucose into fat requires a substantial energy investment. If the costs for prior conversion of glucose into glycogen, as well as for the transport of fatty acid synthesized in the liver to adipose tissue are also included, the cost for conversion of dietary carbohydrate into fat may be assessed at ~25% (7,33). In subjects consuming a Western diet, fatty acid synthesis from glucose appears to be of minor quantitative significance (34,35), as even the ingestion of an unusually large carbohydrate load of 500 g is accommodated by expansion of the glycogen reserves, without increases in body fat (36). Contrary to still commonly held expectations, dissipation of dietary energy by conversion of glucose into fat is therefore not a reason that could explain why high-carbohydrate diets are less conducive to obesity than high-fat diets.

### 4 Costs for Maintaining Energy Reserves

The costs for nutrient storage include not only the ATP expenditure required for their initial incorporation into the body's stores, but also those involved in maintaining and moving the tissues which contain these reserves. The resting metabolic rate increases by ~7–10 kcal/d/kg additional body weight in adult women and men (37). However, owing to the cost of moving the additional weight, this causes a greater increase in daily energy expenditure ranging from 10–15 in sedentary to 20–30 kcal/d/kg additional body weight in moderately active to very active individuals. Typically it takes ~1 year for these costs to be equal to the initial energy investment. The degree of physical activity is thus another factor affecting the cost of energy storage, even though it does not imply any change in the efficiency with which metabolic processes or ATP turnover occur. Furthermore, the self-correcting effect which changes in body weight exert in compensating for deviations from the energy balance is greater in physically active and in “fidgety” subjects (38) than in sedentary individuals, a phenomenon that totally escapes detection when resting metabolic rates are compared.

### 5 Futile Cycles

Interconversion of intracellular substrates can cause ATP dissipation if they involve ATP-consuming reactions (e.g., fructose-1,6-diphosphate hydrolysis by fructose diphosphatase and resynthesis by phosphofructokinase). Such *substrate cycles*, which cause no net change in the organism but dissipate ATP, have sometimes been referred to as *futile cycles*. Elaborate mechanisms have evolved to regulate the activity of enzymes involved in catalyzing opposite transformation so as to prevent high rates of wasteful substrate interconversions. Complete suppression of these interconversions is not always achieved, however, as it may not be compatible with the quick responses needed to allow for rapid changes in ATP production when needed (39). Other intracellular substrate cycles include interconversions of glucose and glucose-6-P, or synthesis and breakdown of phosphoenolpyruvate by enzymes involved in the gluconeogenic pathway. When fatty acids are produced by triglyceride hydrolysis in adipose tissue, some are reesterified on the spot. In spite of this, free fatty acids are released from adipose tissue in amounts greater than used for energy production; the excess is reesterified in the liver, to be reexported to adipose tissue in the form of lipoproteins (14). This also causes ATP dissipation without net change in the system, but the fact that lipolysis proceeds at

higher-than-minimal rates helps to ensure an adequate supply of circulating FFA and promotes fat oxidation, since fat oxidation is enhanced by high circulating FFA levels (40).

It has been difficult to design tracer studies capable of providing accurate estimates of some of these substrate cycling rates, but the available information suggests that they account for only a small percentage of total energy expenditure (41). The increase in peripheral substrate mobilization caused by higher catecholamine levels during overfeeding, and the increased release of various mobilizing hormones during periods of stress cause an increase in substrate traffic, which may account for about one-fourth of the rise in resting metabolic rates under these conditions (42).

There has also been interest in examining the possibility that transfer of reducing equivalents from mitochondrial to cytoplasmic NADH, through a set of reactions involving glycerol-3-phosphate dehydrogenase (GPDH), may alter metabolic efficiency, since only two instead of three high-energy bonds can be generated from cytoplasmic NADH (43). Overexpression of GPDH in transgenic mice considerably reduces their body fat content (44), but the extent to which this enzyme affects the turnover of reducing equivalent is unknown. Its influence would be reflected in the resting metabolic rates, as are the effects of futile cycles.

The activity of substrate cycles tends to be enhanced by thyroid hormones (45) and their potential role in energy dissipation have therefore been of some interest. However, their impact on energy expenditure is far less than that of the ATP-dependent sodium extrusion constantly carried out by the cell membranes' sodium-potassium ATPase, which may account for ~20% of basal energy expenditure, though data to establish this with some certainty are not available (5,46). Proton leakage through the mitochondrial membrane also demands a certain rate of substrate oxidation at rest to maintain a proton gradient sufficient to drive ATP resynthesis, which may account for 20% of energy expenditure (5). Even though these two phenomena do not result in changes in the system, maintenance of  $K^+$  gradients across cell membrane and of  $H^+$  gradients across mitochondrial membranes cannot really be considered to be futile, since these gradients are essential in maintaining membrane potentials and cell integrity. Increases in sodium-potassium ATPase activity induced by thyroxine suggest that enhanced  $Na^+$  pumping may account for increases in energy expenditure caused by elevation of thyroxine levels, though a higher number of ATPase molecules does not by itself cause or prove that  $Na^+$  fluxes are increased. Thyroid status also

appears to affect the rate of proton leakage through the mitochondrial membrane (47).

### C Metabolic Efficiency

When compared to daily energy turnover, the amount of energy retained during growth and during the development of obesity is rather small, amounting to a difference of only a few percent between intake and expenditure. Because a positive energy balance can, in principle, be attributed to excessive intake or to reduced expenditure, there has been considerable interest in the possible significance of even small differences in *metabolic efficiency* for the development, or the prevention of obesity.

Metabolic efficiency can be defined in many ways. The most readily applied approach is to relate physical work output to energy expenditure. During low-intensity exertion, the efficiency of the process appears to be low, because most of the energy expended serves to regenerate the ATP dissipated for maintenance metabolism. The intensity of the workload, relative to resting energy expenditure, is thus the major variable determining the apparent *overall metabolic efficiency*. To obtain a better measure of metabolic efficiency, it is important to relate the amount of work produced to the change in metabolic rate it causes. Typical values for the *net efficiency* of aerobic work range from 25% to 27% in man and animals (2,28). Relating energy deposited in the carcass to total amount of food energy consumed is an important practical consideration in judging *feed efficiency* in the production of meat. As in the case of increasing workloads, overall or *gross nutrient efficiency* rises markedly as the amount of excess energy consumed becomes larger relative to maintenance energy expenditure (Fig. 2). In a situation characterized by rather small changes in body size over time, gross nutrient efficiency is close to zero, which in terms of characterizing potential metabolic differences between lean and obese is essentially meaningless. In trying to assess the efficiency with which food energy is processed, it is therefore important to assess energy retention relative to the amount consumed in excess of maintenance requirements. The accuracy of such an approach is limited, particularly in man, because the maintenance energy requirements account for a rather large fraction of the energy consumed, and because these requirements keep changing as body weight and physical activities vary during the weeks needed to produce measurable changes in body composition. Thus, even small errors in estimating maintenance requirements have a considerable impact on the net efficiency value obtained

**Figure 2** Effect of level of energy intake on “gross” and “net” nutrient efficiencies. Energy expenditure (x) is considered to increase during overfeeding (dissipating 20% of the energy consumed above maintenance requirements), and to decline during underfeeding (attenuating the energy deficit) by 5%. “Gross nutrient efficiency” describes the % of energy retained relative to energy consumed (■). It is determined primarily by the level of energy intake. “Net nutrient efficiency” (●) describes the fraction of the energy consumed above maintenance levels that is retained. It is greatly affected by minor errors (i.e., a 5% overestimate  $\Delta$ , or a 5% underestimate  $\nabla$ ), particularly in the range of modest excess intakes.

(Fig. 2), and the reliability of such evaluations in characterizing potential differences in metabolic efficiencies is questionable.

Differences in ATP dissipation through ion pumping, futile cycles, and protein turnover are all included in the measured resting metabolic rates. These are closely correlated with the size of the fat-free mass and the fat mass, and resting energy expenditures are thus higher in obese than in lean subjects of the same heights (48), though a certain degree of variability among individuals remains. The importance often attributed to such differences appears to be founded on the presumption that changes in energy expenditure will not be offset by changes in energy intake. Under conditions where energy intake could be “clamped” at some particular level, a 5% difference in resting energy expenditure would be offset by a difference in body weight of 5–8 kg

in a sedentary individual, or less in a physically active individual. When access to food is not restricted, energy balance is determined overwhelmingly by the factors influencing food intake, and by the adjustments in food intake that serve to compensate for recent substrate imbalances, rather than by the overall rate of energy turnover (49). Pregnancy, for instance, leads to the deposition of a few kg of additional fat in spite of an increase in resting energy expenditure (50). Arguments about the possible role of minor differences in resting metabolic rates in promoting or preventing obesity and in playing a role in body weight maintenance are therefore hollow if they are not linked to considerations of the factors controlling energy intake; if they fail to do so, they may end up creating a conceptual trap.

#### D Cold Exposure

Exposure to low environmental temperatures raises energy expenditure and can modify the composition of the fuel mix oxidized. Thus the RQ of ad libitum-fed rats was 0.92 at thermal neutrality, 0.87 during acute cold exposure (acclimation to 25°C and test at 15°C), and 0.77 at chronic cold (acclimation and test at 15°C) (51). This is consistent with other data showing a preferential contribution of lipid to nonshivering thermogenesis in cold-exposed animals (52,53).

The impact of cold exposure has also been studied in man. Acute exposure to a temperature of 5°C causes resting  $O_2$  consumption to nearly double after 2 hr (54). Under these conditions changes in the respiratory exchange ratio over the 2 hr of cold exposure were not significant at rest and during exercise. Spending a day in a respiratory chamber at 16°C was perceived to be uncomfortably cool, and rectal temperatures in the morning were 0.11°C lower than when the ambient temperature was 24°C. Yet this elicited only a 2% increase in 24-hr energy expenditure, covered by increased glucose oxidation (55). When one considers that individuals generally adjust clothing when exposed to cold, the changes in resting energy expenditure induced by a cold environment are not likely to be substantial. Since a wide range of cold exposures can be survived, the use of glucose obviously can adjust itself to carbohydrate intake, regardless of the stimuli that may cause changes in the RQ at the onset of cold exposure. However, one may keep in mind some incidental observations, whose validity remains to be established. For instance, cold exposure may elicit vigorous movements reflecting efforts to restore blood flow and to raise body temperature, or on the contrary, it may inhibit motion.

There also seems to be a prevailing perception of increased hunger when subjects are exposed to a cold environment, and of a tendency to gain fat during the cold season.

## II MEASUREMENT OF SUBSTRATE OXIDATION AND ENERGY EXPENDITURE

Changes in the body's substrate content due to metabolism can be calculated from CO<sub>2</sub> production, O<sub>2</sub> consumption, and urinary nitrogen excretion data. This experimental approach has provided a wealth of data on human energy expenditure (28,29,56,57). The results of this "indirect calorimetry" are consistent with data obtained by direct measurement of heat production, i.e., "direct calorimetry" but the former has the advantage of providing information on the relative amounts of carbohydrate, fat, and protein used. Attention must be given to careful calibrations to permit accurate determinations of the respiratory quotient and hence of the relative proportions of carbohydrate and fat oxidized. When combined with precise assessment of the amounts of nutrients consumed, indirect calorimetry can establish substrate or nutrient balances over periods of 1 day or several days, which are far too small to be established by body composition measurements (27). In recent years, indirect calorimetry has been complemented by the application of the doubly labeled water (DLW) technique, which has allowed to determine energy expenditure (but not substrate balances) in free-living subjects (48).

### A 24-Hr Energy Expenditure by Indirect Calorimetry Using Metabolic Chambers

Modern gas analyzers and online data processing have stimulated the construction of respiratory chambers in which subjects can be studied over 24-hr periods or for several consecutive days with reasonable comfort. In such a confining environment, sedentary behavior can be modified by prescribed amounts of exercise on a treadmill or equivalent device (56,58). Reproducible measurements of daily energy expenditure can be achieved that are accurate within a few percent. Under the best conditions, errors in carbohydrate and fat balances can be reduced to  $\pm 20$  and  $\pm 10$  g/d, respectively (59). Numerous studies have been performed to quantify daily energy expenditure and substrate balances, notably to compare differences in energy expend-

iture in lean and obese subjects and the effects of overfeeding. Among other things, they indicated that a high 24-hr RQ is a risk factor for long-term body weight gain (60,61). Twenty-four-hour indirect calorimetry also provides the means to study the adjustment of the fuel mix oxidized to changes in the diet's composition (26,27,62). Other important results relate to the role of sympathetic nervous system activity on daily macronutrient utilization (63) and to the measurement of net lipogenesis induced by deliberate and sustained overconsumption of carbohydrates (33).

### B 24-Hr Energy Expenditure Based on Heart Rate Measurements

Continuous heart rate monitoring offers a possibility to measure energy expenditure around the clock, but it requires that the relationship between heart rate and oxygen consumption be established individually. The approach has been validated by concomitant indirect calorimetry and DLW measurements (64,65). This "heart rate O<sub>2</sub> method" has been successfully used in trained and untrained individuals to measure daily energy expenditure and compensations in non-prescribed daily activities (66).

### C Energy Turnover in Free-Living Subjects

The lack of means to assess energy expenditure and substrate oxidation under free-living conditions has long been a major barrier for obesity research. This problem was finally resolved thanks to a method conceived by Lifson et al. in the 1950s (67) to assess energy expenditure in small animals. It is based on the administration of an initial dose of <sup>2</sup>H<sub>2</sub><sup>18</sup>O. The difference in the rate of <sup>18</sup>O elimination, which is lost in water and CO<sub>2</sub>, relative to the rate of deuterium (<sup>2</sup>H) elimination, lost as water only, allows assessment of the CO<sub>2</sub> production rate, which correlates closely with oxygen consumption and energy expenditure (68). It took nearly three decades before the first paper describing the application of this DLW technique in humans was published (69). A number of methodological problems and potential pitfalls were encountered, leading on occasions to physiologically impossible results. Comparison of results obtained by several groups of investigators have confirmed the validity of the method, and the conditions and calculations for its successful applications have been defined with increasing detail (70).

Measurements of energy turnover by the DLW method in sedentary subjects led to downward revisions

of common assumptions about minimum maintenance requirements (71). Other studies (72) led to a reduction of the additional energy allowances during pregnancy from 500 to 300 kcal/d (50). The long-held belief about the low maintenance energy requirements in overweight “small eaters” was shown to be attributable to under-reporting of habitual food intake (48,73,74). It also became possible to assess energy expenditure under conditions of extreme physical demand, demonstrating energy turnovers reaching 5000–8000 kcal/d in bicycle racers (75). According to Goran and Poehlman (76), the technique can be used to evaluate compensations in energy expenditure in response to exercise training.

#### D Diet-Induced Thermogenesis

Diet-induced thermogenesis (DIT) includes all increases in resting energy expenditure induced by food consumption, which comprise the TEF during the postprandial periods (see Chap. 25), as well as increases in resting energy expenditure between meals induced by excessive food consumption. In man, most of these increments in resting energy expenditure are explained by “obligatory” factors such as digestion, metabolism, and storage of macronutrients including the cost for the synthesis of the constituents of newly formed tissues, and the physiological processes essential for their maintenance (31). “Nonobligatory” or “facultative” components contributing to DIT are catecholamine-mediated increases in energy expenditure elicited by carbohydrate consumption during the TEF, and the stimulation of substrate oxidation in BAT through activation of a protein-conducting pathway elicited by SNS innervation, which has the effect of uncoupling substrate oxidation from oxidation phosphorylation (8,9). The quantitative importance of facultative thermogenesis can be substantial in animals, and suppression of BAT thermogenesis greatly enhances the development of obesity in animals (10).

Investigations into the physiological role of BAT in humans has not yielded comparable results. Although the presence of BAT has been demonstrated in humans (77), experimental evidence suggests that skeletal muscle is the main site of cold-influenced thermogenesis (78). A number of overfeeding studies have been performed to evaluate the potential role of DIT in human studies in which energy expenditure was directly measured either by indirect calorimetry or by the DLW method, but dissipation of excess dietary energy through *Luxusconsumption* (a term sometimes used to describe elevated DIT during overfeeding) could not be detected. Most of the increase in 24-hr energy expenditure found during overfeeding could be explained by

the cost of substrate handling, tissue accretion, and maintenance of an enlarged body (79–82).

#### E Physical Activity

The metabolic changes observed during and for many hours after exercise can substantially modify macronutrient utilization and energy expenditure. As depicted in Figure 3, RQ increases during exercise, indicating that initially carbohydrate is the main substrate contributing to the increase in energy production. The figure also illustrates that the RQ during exercise is influenced by numerous factors such as the intensity and duration of exercise. It is well established that RQ is increased to a greater extent by high than low to moderate intensity exercise (83) and that the RQ progressively declines with increasing exercise duration. Exercise RQ also tends to be lower in trained than in nontrained individuals (84).

Resting RQ can be reduced for 15–20 hr after prolonged vigorous exercise (85,86). However, no data are available to establish how long and how much the resting RQ is decreased after exercise. Since high intensity exertion is as effective in inducing fat loss as aerobic work (87), one can infer that high-intensity exercise must have a substantial effect in enhancing postexercise lipid oxidation. This may be due to the glycogen depletion which it induces, but another important observation is that high-intensity training increases the potential of skeletal muscle to oxidize lipid to a greater extent than aerobic exercise of moderate intensity, at least as judged by the rise in muscle  $\beta$ -hydroxy-acetyl-CoA dehydrogenase (HADH) activity (87).

Since exercise permits weight maintenance at lower degrees of adiposity, it substitutes for an expansion of

**Figure 3** Variations in respiratory quotient during a low- and a high-intensity exercise. (From Ref. 83.)

the fat mass in bringing about rates of fat oxidation commensurate with fat intake. The overall effect of exercise is therefore to increase fat oxidation more than glucose oxidation (88). Human subjects who are high fat oxidizers during exercise consumed less food when they subsequently could eat at will, and they were more likely to be in negative energy and lipid balance compared to low fat oxidizers (89,90). Of particular interest is the hypothesis that exercise is likely to induce greater fat losses in obese individuals who have a high capacity to oxidize fat during and after exercise. The potential link between exercise-induced changes in substrate oxidation and postexercise energy intake and balance needs to be investigated.

### F Variability of Daily Energy Expenditures, Intakes, and Balances

Daily energy expenditures of subjects confined to a respiratory chamber are substantially lower than in free-living subjects (91,92), and the spontaneous variations in physical activity associated with free-living conditions cannot manifest themselves. On the other hand, DLW measurements, which provide assessment of overall energy expenditure over periods of 7–10 days, do not allow to define variations in energy expenditure from day to day. Future methodological developments may permit us to assess substrate oxidation under free-living conditions, a potential suggested by recent animal studies (93). These variations must be evaluated on the basis of estimates calculated from activity logs. Many more data are available on daily food intakes. The coefficients of variations for intraindividual daily food intake are large, averaging  $\pm 22\%$  among adults (94), and ranging from  $\pm 15$  to  $\pm 33\%$  in children (95). It seems to be generally held that variations in food intake are substantially greater than variations in energy expenditure. Deviations from the energy balance are thus probably comparable in size to the variability in intakes. The extent of daily variations in food intake and energy expenditure, and the size of daily deviations from energy balance potentially influence body weight maintenance, inasmuch as changes in food intake in response to positive or negative energy balances may not occur with the same accuracy (96,97).

### III FACTORS DETERMINING SUBSTRATE OXIDATION RATES

Overall energy expenditure is determined by an individual's size and physical activity, and it is only modestly

affected by nutrient intake. Amino acid oxidation rates vary only moderately, increasing somewhat after protein ingestion (17) and during vigorous exertion (98), but declining when protein intakes are reduced. By contrast, the organism is able to rapidly and powerfully alter the relative contributions made by glucose and FFAs to the fuel mix oxidized. Such great flexibility in fuel utilization is made possible by the ability of most cells to interchangeably use metabolic intermediates derived from carbohydrates, fats, and proteins to regenerate ATP. It allows adaptation to food supplies varying widely in their macronutrient distribution (provided that proteins provide at least some 10%, and essential fatty acids at least 1–2% of total energy) (50).

### A Substrate Oxidation by Different Tissues

The contribution made by various tissues to the body's oxygen consumption, or in effect to overall energy turnover, is described in Table 2 (16), whereas their contribution to overall fuel utilization also depends on their metabolic functions (99). The central nervous system's rate of energy expenditure is particularly high for its size (2% of body weight), as it accounts for nearly 20% of resting energy expenditure in adults (100). Since it cannot use FFA, it is critically dependent on an adequate supply of glucose ( $\sim 80$  mg/min). However, after adaptation to starvation, ketone bodies can provide about two-thirds of the brain's energy needs (101). Red blood cells also depend on glucose, as they lack mitochondria and must generate ATP by substrate-level phosphorylation during glucose degradation to lactate. They use  $\sim 1$  g of glucose per hour (100,102), but this has very little impact on the body's fuel economy, since 98% is converted to lactate (102), which can be reconverted into glucose by the liver.

**Table 2** Relative Oxygen Consumption of Different Tissues

|                  | At rest     | Light work  | Heavy work  |
|------------------|-------------|-------------|-------------|
| Brain            | 0.20        | 0.20        | 0.20        |
| Abdominal organs | 0.25        | 0.24        | 0.24        |
| Kidneys          | 0.07        | 0.06        | 0.07        |
| Skin             | 0.02        | 0.06        | 0.08        |
| Heart            | 0.11        | 0.23        | 0.40        |
| Skeletal muscles | 0.30        | 2.05        | 6.95        |
| Other            | <u>0.05</u> | <u>0.06</u> | <u>0.06</u> |
| Total            | 1.00        | 3.00        | 8.00        |

(whole body at rest = 1.00; actual value near  $3.8 \text{ mL O}_2 \text{ min}^{-1} \text{ kg}^{-1}$ )  
Source: Ref. 16.

About one-quarter of resting energy expenditure occurs in the splanchnic bed (103). It has become evident that the gut derives a substantial part of its energy by partial degradation of glutamine, its glucogenic moiety reaching the liver (30). Conversion of the glucogenic moieties of the amino acids is a feature of amino acid degradation even under fed conditions (30). One can therefore presume that conversion of pyruvate to acetyl-CoA in the liver is effectively inhibited during most of the day, a conclusion which is consistent with the lack of hepatic fatty acid synthesis under habitual living conditions (34).

The heart accounts for ~10% of resting energy expenditure. Its constant and critical requirement for fuel is aptly matched by its ability to utilize all types of substrates that may be available, including notably some of the lactate produced by working skeletal muscles (104). Although skeletal muscles make up three-quarters of the body cell mass, the muscle accounts for only 20–30% of energy expenditure at rest (5,100). During exertion substrate oxidation in the muscle mass can increase 20-fold (Table 2) (16), with the increase being even greater in particular muscle groups. In the postabsorptive state, fatty acids are the main oxidized fuel in muscle (99,105), whereas during exertion, great demands are initially placed on the muscles' own glycogen reserve, with a subsequent shift toward increasingly greater use of fatty acids, mobilized from muscle fat stores as well as from adipose tissue (Fig. 3). Since muscle is ready to oxidize fatty acids as well as glucose (40,106), exercise enhances the body's ability to adjust the use of glucose and fatty acids to the dietary supply (Fig. 4). This may explain why fat oxidation can more readily keep up with fat intake in physically active adults and in most children and adolescents as they are naturally more physically active than adults.

## B Glucose Turnover and Glucose Oxidation

Some of the glucose utilized by various tissues is converted to lactate (*Cori cycle*) or to alanine (*glucose-alanine cycle*), which are readily reconverted into glucose by the liver. Glucose turnover is thus substantially greater than the rate of glucose oxidation. Carbohydrate oxidation determined by indirect calorimetry describes the change in the body's carbohydrate content. It should be noted at this point that the energy content of glycogen (4.18 kcal/g) and of glucose (3.7 kcal/g) differ by 10% (because 1 mol of water is removed when glucose is incorporated into the glycogen or starch). It is thus important to be consistent and to specify which of the two is being considered. During the

**Figure 4** Impact of physical activity (described as the ratio of total to resting energy expenditure) on the contribution of skeletal and heart muscle metabolism to total energy turnover. (Calculated from the information provided in Table 3, assuming that half of the exercise-induced increase in energy expenditure is due to work of light and half to work of heavy intensity.)

degradation of amino acid mixtures, 55–60 g of glucose is generated by gluconeogenesis from 100 g of protein, and this occurs even in the fed state when plenty of glucose is available (30). In indirect calorimetry calculations, the oxidation of the glucose formed by gluconeogenesis from amino acids is included in the coefficients describing  $\text{CO}_2$  production and oxygen consumption from protein. Glucose oxidation determined with the help of tracers is thus measurably greater than carbohydrate disappearance established by indirect calorimetry. Similarly, the glycerol liberated during the oxidation of triglycerides (about 10 g/100 g triglycerides, or 5% of the triglyceride energy) is converted into glucose before being oxidized, the  $\text{CO}_2$  produced and the oxygen consumed being again included in the coefficients for fat oxidation. This is why the RQ for triglyceride oxidation (0.71) is slightly higher than that for fatty acid oxidation (0.70) (15).

## C Starvation Ketosis

The body's glycogen reserves are limited to a few hundred grams (107), and during periods of starvation or marked carbohydrate deprivation they can provide

enough glucose to the brain for a few days only (101,108). Survival during starvation is made possible by the induction of ketogenesis in the liver, when insulin levels become very low and FFA levels concomitantly rise (109). Acetoacetate plus  $\beta$ -hydroxybutyrate production reaches 100–120 g/day by the third day of total starvation. Circulating ketone body levels rise only progressively, as some are used by skeletal muscle during the initial days of starvation, since muscle is ready to use ketone bodies whenever they are produced—e.g., during prolonged physical efforts. When starvation ketosis is fully developed, ketone body levels reach a plateau of 5–6 mM. At this level, they provide about two thirds of the brain's fuel needs, but 5–15 g of  $\beta$ -hydroxybutyrate and acetoacetate is lost in the urine per day. The urinary loss of limited amounts of these anions can be offset by excretion of N in the form of ammonium instead of urea. This provides the cations needed, thereby preventing the development of metabolic acidosis (101). In the total absence of insulin, ketone levels rise to far higher levels, in part because the overabundance of circulating fuels decreases peripheral ketone body utilization. Urinary losses then become far greater, leading to metabolic acidosis.

## D Regulation of Substrate Oxidation

In view of the critical need to maintain high ATP levels, of the functional importance of proteins, and of the need to ensure a sufficient supply of glucose for the brain, the main goals for metabolic fuel regulation are to assure the distribution of substrates in amounts sufficient to support oxidative phosphorylation at the required rates, to maintain homeostasis, and to bring about the use of metabolic fuels in such proportions as to minimize changes in protein content and to maintain glycogen levels within a desirable range. This is detrimental to the body's ability to regulate the fat balance (110), which is not a problem in the short term, since such gains or losses of fat are very small in comparison to the body's large fat stores (50,000–200,000 kcal in adults and even more in obese subjects). However, if the fat balance is not accurately regulated, neither is the overall energy balance.

### 1 Hormonal Regulation of Substrate Availability

The composition of the fuel mix oxidized is mainly controlled by adjustment of circulating substrate and hormone levels. These levels are markedly influenced by nutrient intake. The impact of changes in substrate

levels on their rates of utilization during the postprandial phase is enhanced by the release of insulin, which promotes transport and storage of glucose, amino acids, and fats while inhibiting the release of glucose from the liver and of fatty acids from adipose tissue. The decline in circulating FFA levels, brought about by the antilipolytic action of insulin complemented by the direct and indirect effects of insulin in activating pyruvate dehydrogenase (PDH) (111) lead to an increase in glucose oxidation and to a commensurate decrease in fatty acid oxidation. The decline in insulin secretion when glucose absorption from the gut is completed, complemented by the release of catecholamines and glucagon, activates the mobilization of the body's glycogen and fat reserves to assure an adequate supply of glucose and FFA in the circulation (112,113). These effects are greatly enhanced when the demand for metabolic fuels is magnified by physical efforts.

### 2 Body Composition and Fuel Composition

Between meals and efforts, the composition of the fuel mix oxidized is influenced by the size of the body's protein pools, the degree of repletion of its glycogen reserves, and the size and distribution of the adipose tissue depots. This is the simple consequence of the fact that the influence of hormones on substrate fluxes is determined by the intensity of the endocrine signals and by the size of the targets they influence, and that hormone secretion is itself influenced by prevailing substrate levels.

The gains or losses that occur when the oxidation of glucose, FFA, and amino acids do not match their intakes lead to changes in body composition until the impacts of these changes on the composition of the fuel mixture oxidized complement the body's endocrine and enzymatic regulatory mechanisms such that the fuel mix oxidized matches, on average, the macronutrient distribution in the diet (114). As evidenced by the commonly observed stability of body composition, the effect of these changes in bringing about the adjustment of fuel composition to nutrient intake is universal and remarkably effective, but the body composition for which this adjustment is achieved can vary greatly between individuals, depending on interactions between inherited and circumstantial factors (113).

### 3 Adjustment of Amino Acid Oxidation to Protein Intake

The ability to quantify changes in the body's protein content by monitoring the N balance has led to the early

recognition of the organism's tendency to maintain a stable protein content, or to allow for an appropriate rate of protein accretion during growth or recovery from disease or undernutrition. This occurs regardless of differences in the carbohydrate-to-fat ratio of the diet. Detailed metabolic studies during starvation have revealed how the organism is able to minimize protein losses during food deprivation (112). Its regulatory features also enable it to avoid needless and costly buildup of its protein content when high-protein diets are consumed, but the mechanisms accounting for this are not well understood. Daily protein intakes, generally between 50 and 100 g in adults, are small compared to the body's total protein content, of which about half (~6 kg) is intracellular and engaged in active turnover. When changing from situations of high to low protein intake, or vice versa, a few days are required before N balance is again achieved. The small gains or losses of proteins which are thereby incurred appear to be prerequisites for the reestablishment of N balance, demonstrating that relatively minor changes in protein content play a significant role in the adjustment of amino acid oxidation rates to protein intake. Small gains or losses of protein thus appear able to influence amino acid oxidation and to bring about the corrective responses needed to compensate for the small deviations from even N balance which occur from day to day.

#### 4 Adjustment of Glucose Oxidation to Carbohydrate Intake: Influence of Glycogen Stores

The body's glycogen stores (200–500 g in adults) (107) are not much larger than the amount of carbohydrate usually consumed in one day. In view of the importance of the hepatic glycogen stores in maintaining stable blood glucose levels and of muscle glycogen availability in permitting appropriate muscular responses to sudden demands, biological evolution led to regulatory mechanisms (including endocrine signals) that give high priority to the adjustment of carbohydrate oxidation to carbohydrate availability (114,115). Glucose oxidation thus declines rapidly when ingestion of food fails to replenish the glycogen reserves in a timely fashion. On the other hand, the body's metabolism quickly shifts to the predominant use of glucose after carbohydrate ingestion. This manifests itself by a prompt postprandial rise in the RQ to an extent and for periods determined by the amounts and the types of carbohydrates consumed. This response is important since inappropriate curtailment of fat oxidation when carbohydrates provide the bulk of food energy would lead to a negative

fat balance, or require substantial de novo fat synthesis (at substantial metabolic cost) during part of the day.

After large carbohydrate intakes, high rates of carbohydrate oxidation persist for many hours, allowing dissipation of the built-up glycogen reserves (36). If massive consumption of carbohydrates is deliberately kept up for several days, glycogen stores become saturated and further accumulation is prevented by conversion of glucose into fat, which may drive the overall RQ to values  $> 1.0$  (33). However, the regulation of appetite is such that glycogen levels are spontaneously maintained far below the range at which de novo lipogenesis is induced, and loss of carbohydrate by conversion into fat is quantitatively insignificant ( $< 5$  g/d) in adults consuming mixed diets (34,35).

The degree of repletion of the body's glycogen stores thus greatly influences the contribution made by glucose to the fuel mix oxidized. Gains or losses of glycogen are therefore effective in bringing about changes in glucose oxidation when the influx of carbohydrate varies (26,116) or when physical exertion has caused unusual glycogen depletion. As in the case of protein, this is in part a simple mass effect, since insulin is less effective in curtailing glucose release from the liver when the hepatic glycogen reserves have been built up (117).

#### 5 Adjustment of Fat Oxidation to Fat Intake: Influence of Adipose Tissue Mass and Distribution

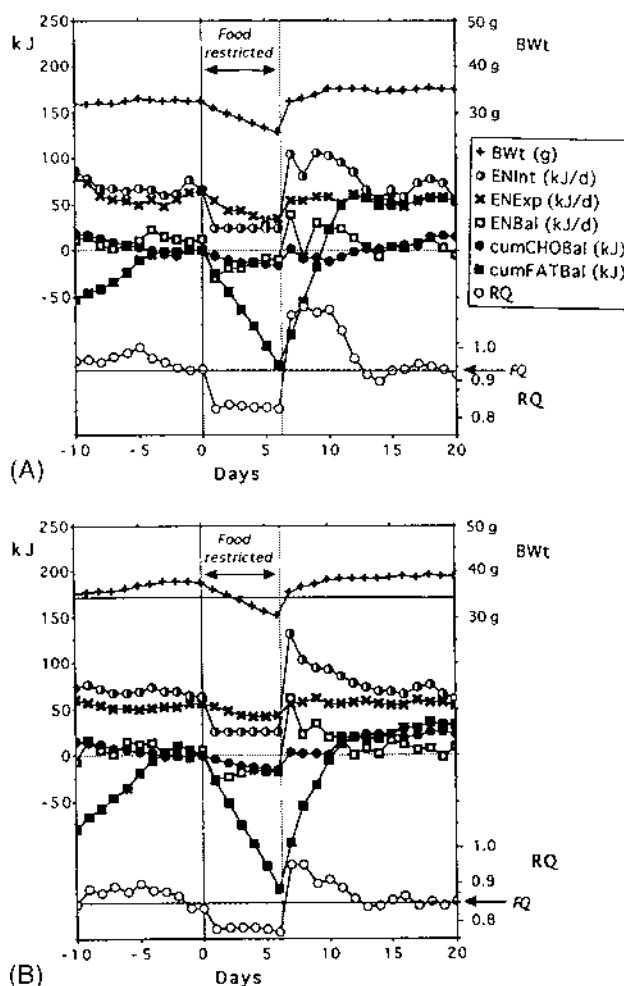

Because amino acid and glucose oxidation rates adjust themselves to the amounts of protein and carbohydrate consumed, fat oxidation is determined primarily by the gap between total energy expenditure and the amounts of energy ingested in the form of carbohydrates and proteins (49). Fat oxidation rates are thus set primarily by parameters unrelated to the body's fat economy, rather than by the amounts of fat consumed. Furthermore, short-term gains or losses of fat are so small in comparison to the body's large fat stores that they are unlikely to elicit changes in food intake or in fat oxidation. Given the lack of direct regulatory mechanisms serving to adjust fat oxidation to fat intake (118), one may wonder why body fat contents should nevertheless tend to remain fairly constant, even when diets differing widely in fat content are consumed.

Various factors contribute to this adjustment. For instance, if fat replaces carbohydrate in meals, the postprandial inhibition of fat oxidation is lessened, since the postprandial rise in RQ is related primarily to the amount of carbohydrate consumed. The presence of fat in a meal delays its absorption, and this will also

attenuate the post-prandial rise in the RQ. When meals containing very large amounts of fat are consumed (e.g., 80 g) (119), some of the fatty acids liberated from chylomicrons by lipoprotein lipase escape capture by adipose cells and enter the pool of circulating free fatty acids, promoting fat oxidation, though only modestly (e.g., 10 g in 6 hr) (119). Finally, glycogen levels may tend to be maintained in a lower range when the proportion of carbohydrate in the diet is reduced, resulting in lower insulin levels and hence higher rates of FFA release and oxidation between meals (26). However, this cannot be expected to produce an exact compensation, since FFA levels and oxidation rates are controlled by insulin whose secretion is determined primarily by the need to maintain appropriate blood glucose levels.

While short-term errors in the fat balance are too small to affect the size of the body's fat stores, circulating FFA levels, fat oxidation, or food intake, the cumulative effects of repeated imbalances between fat intake and fat oxidation can in time lead to substantial changes in the size of the adipose tissue mass. Expansion of the fat mass leads to higher FFA levels and turnover (120). The role that change in the adipose tissue mass plays in the establishment of the steady state of weight maintenance can be inferred by considering the changes in substrate balances induced by a period of food restriction. After a few days on reduced intake, or after the first few days during a subsequent period of weight regain, further losses or gains of protein and glycogen are minimal and account for only a minor part of the energy imbalance. Owing to the contribution made by endogenous fat to the fuel mix oxidized during caloric deprivation, the average RQ is lower than usual during the period of weight loss. During weight regain, on the other hand, the 24-hr RQ is greater than usual, reflecting the oxidation of a fuel mix containing a higher proportion of glucose than the diet, as part of the fat consumed is stored. At some point, the situation is encountered for which the two conditions necessary for weight maintenance are again satisfied; i.e., food intake is commensurate with energy expenditure and the average RQ matches the diet's "food quotient" (FQ), which describes the ratio of  $\text{CO}_2$  produced to  $\text{O}_2$  consumed during the biological oxidation of a representative sample of the diet (31,114). What one would like to know in this regard is whether this should be attributed to the increase in energy expenditure associated with weight gain, or whether some other phenomenon is involved.

This issue could be precisely examined in mice (Fig. 5) (113). The unusually elevated rate of food consump-

**Figure 5** Effect of temporary food restriction on body fat and glycogen content in mice. The figure shows average body weights, cumulative carbohydrate and fat balances, and daily energy expenditures, intakes, and balances in two groups of five fed female CD1 mice, during a 6-day period of food restriction to 40% of average ad libitum intake, and during the preceding and following days of ad libitum intake. One group was maintained on a diet containing 13% (panel A), the other on a diet containing 41% (panel B) of dietary energy as fat, 19% as casein and the balance as corn starch plus sucrose (1:1). (From Ref. 113.)

tion following a period of food restriction abated when the fat mass had regained its initial size. The balance between energy expenditure and food intake was not achieved by an increase in energy expenditure due to weight gain, but by a decrease in food consumption, as the degree of adiposity was approached, for which the RQ became again equal to the FQ. Enlargement

of the fat depots thus promotes fat oxidation, just as well as filled glycogen stores promote glucose oxidation (27,117), but the increase in fat oxidation brought about by expansion of the adipose tissue mass is *chronic*, rather than related to recent food consumption. This chronic effect can be enhanced by a type of insulin resistance typically induced by excessive fat accumulation, whose effect is to promote fatty acid, but to inhibit glucose oxidation (49,61,121). The influence of the adipose tissue mass on the composition of the fuel mix oxidized explains why the particular body composition will in time be reached (or approached) for which the fat oxidation is commensurate with fat intake.

## 6 Alcohol Intake and Oxidation

Alcohol is not generally considered to contribute greatly to dietary energy intake, but alcohol sales data indicate that alcohol provides ~5% of overall energy intake in the United States. In the Quebec Family Study, alcohol energy represented 17% and 11% of daily energy intake of adult males and females, respectively, in the upper quartile for alcohol intake (122).

Many epidemiological studies have investigated the association between alcohol consumption and the intake of macronutrients. Some reported a negative association between alcohol and carbohydrate intake (122,123); others found reduced protein, fat, and carbohydrate intake in moderate alcohol drinkers (124). However, other studies showed that energy and macronutrient intakes were not altered by alcohol intake, suggesting that alcohol energy often represents just an additional source of dietary energy (125–129). Studies on the impact of alcohol intake on energy expenditure show that the thermic effect of alcohol is slightly higher than that of carbohydrate, but lower than that of protein (130). Alcohol drives its oxidation, regardless of the level of other fuels, but only up to a rate that covers a minor fraction of total energy turnover. The maximal rate of alcohol oxidation varies among individuals, being generally higher in men than in women, and enhanced in habitual alcohol consumers (131). In examining the impact of alcohol oxidation on the use of other fuels, one sees that its main effect is to reduce fat oxidation (129,132). The inhibitory effect of alcohol on fat oxidation means that alcohol intake is equivalent to fat intake in influencing the fat and energy balances. Alcohol consumption was indeed found to raise total energy intake, particularly when a high-fat diet was consumed (Fig. 6) (122), in a manner that could not be explained by the high energy density of

**Figure 6** Effect of dietary fat content and alcohol on daily energy intake (means  $\pm$  SE). (From Ref. 122.)

the items consumed (133). Inactive individuals reporting a high fat and alcohol intake are characterized by increased subcutaneous adiposity, particularly in the trunk area (122).

## IV SUBSTRATE BALANCES AND WEIGHT MAINTENANCE

When the steady state of weight maintenance has become established, the concept of “nutrient partitioning” is rather meaningless, since over a period of a few days all the nutrients consumed are oxidized, whereas the type of nutrient retained preferentially varies from day to day to compensate for short-term deviations from equilibrated substrate balances. It is the nature of these compensatory responses that needs to be examined to understand what brings about body weight stability.

### A Fuel Composition and Energy Balance

Because of the organism’s tendency to adjust glucose oxidation to carbohydrate intake and to maintain stable glycogen stores, the fuel mix oxidized on days during which excess food is consumed is enriched in carbohydrate. This manifests itself by an elevated 24-hr RQ that reveals that fat oxidation is inhibited on such days in spite of increased intake (114). Excess energy will therefore be retained primarily in the form of fat. When food consumption is insufficient to cover energy expenditure, the substrates obtained from food have to be supplemented by drawing on the body’s energy reserves,

primarily from endogenous fat, in order to prevent excessive glycogen losses. The addition of endogenous fat to the fuel mix oxidized causes the 24-hr RQ to be lower than on days during which energy balance is achieved. There is thus a strong positive correlation between the RQ and the energy balance (114,134,135). Figure 7 (left panel) shows that the relationship between energy balance and RQ depends on the carbohydrate content of the diet. Solid lines show the correlations for diets providing 25%, 40%, or 55% of dietary energy as fat, assuming that carbohydrate balance is exactly preserved. The slope of these correlations is attenuated when part of the imbalance in the energy balance is absorbed by gains or losses of glycogen, as shown by the dotted lines, which are based on the assumption that 20% of the energy imbalance is absorbed by changes in the glycogen stores.

### B RQ/FQ Concept and Energy Balance

To avoid ambiguity about the implications which a particular RQ value may have in judging whether the fuel mix oxidized contains more or less fat than the diet, it is convenient to compare the RQ to the FQ. The relationship between RQ and energy balance can be normalized by considering the RQ/FQ ratio in relation to the ratio of energy intake divided by energy expenditure (right panel of Fig. 7). That the slopes of the lines

are slightly different for different diets does not deter the fact that RQ/FQ ratios  $> 1.0$  imply positive energy balances, whereas RQ/FQ ratios  $< 1.0$  indicate negative energy balances. Weight maintenance, which depends on protein, carbohydrate, and fat balances being all close to zero, corresponds to the situation where the respiratory quotient is equal, on average, to the diet's FQ (114).

The need to satisfy the  $RQ = FQ$  condition creates constraints in the system, as it shows that a balance must be reached between the influences which the body's glycogen stores and the size of the adipose tissue exert on the relative proportions of glucose and FFA being oxidized (113,114). This creates a reason for a particular degree of fatness to become established as long as an individual's diet and lifestyle, as well as habitual glycogen levels, are constant (cf. Fig. 5). It is therefore not necessary to postulate the existence of some mysterious set-point to explain body weight stability.

### C Importance of Food Intake Regulation and Variations in Energy Expenditure in Bringing About Weight Maintenance

Numerous factors capable of influencing food intake have been recognized and studied, but their relative importance and contributions to weight maintenance have been difficult to establish in man, in whom non-

**Figure 7** Relationships among the RQ, the RQ/FQ ratio, and energy balance, assuming that carbohydrate balances are equilibrated (solid lines) or that 20% of the energy imbalances are absorbed by gains or losses of glycogen (dotted lines). (From Ref. 135.)

physiological factors contribute to stabilize or to alter food consumption. Whatever the mechanisms may be, the drive to eat provides for the maintenance of glycogen levels adequate for carrying out habitual workloads and sufficient to prevent hypoglycemia. On the other hand, spontaneous restraint of appetite keeps glycogen levels well below the range for which appreciable rates of de novo lipogenesis would be induced, even when there is free access to a large variety of appetizing food (33,36). Regulation of food intake also prevents overloading the digestive system (136), but this does not prevent the occurrence of substantial day-to-day deviations from energy and substrate balances, or the existence of individual weekly patterns of food intake (137). In spite of considerable short-term deviations from energy balance, most individuals maintain stable body fat contents during prolonged periods of their lives. Since changes in energy expenditure can only modestly attenuate the impact of excessive or insufficient food intakes, it is evident that weight stability is achieved through corrective changes in food consumption and that these adjustments are effective in compensating the daily energy imbalances which occur in free-living individuals (113).

## **D Body Composition for Which Substrate Oxidation Matches Nutrient Intake**

### **1 Impact of Dietary Fat Content**

One of the most significant changes in dietary habits during the 20th century was a marked increase in the fat content of the diet, generally believed to have contributed significantly to the increased incidence of obesity in affluent societies (89,138,139), although other factors (113), notably a reduced level of physical activity, are important contributory factors (140). The overfeeding associated with the consumption of mixed diets providing substantial amounts of fat can be attributed in part to the high energy density of high fat foods (141), to the inability of fat intake to promote fat oxidation (118,142), and to *passive overconsumption* due to the failure of dietary lipid to promote an adequate level of satiety, as suggested by the fact that fat preloads suppress subsequent energy intake less than carbohydrate preloads (143,144). Animal studies show that the steady state of weight maintenance under ad libitum feeding conditions becomes established for higher body fat contents as the fat content of the diet increases, apparently because expansion of the fat mass is required to raise fat oxidation (113,114). This supports the concept that obesity represents an adaptation to high fat diets (145). A certain predilection for fat in

the foods consumed has often been noted in overweight subjects, and epidemiological data show correlations between dietary fat consumption and adiposity (89,138, 146,147).

### **2 Impact of Physical Activity**

Vigorous physical activity is known to influence body weight and fat stores, and it has been repeatedly observed that obese individuals tend to be less physically active than lean subjects. The Canada Fitness Survey demonstrated that individuals reporting regular practice of vigorous activities were leaner than those not performing such activities (148). In addition, obese individuals who had managed to lose weight and maintained an exercise routine regained less weight than those who did not (149). The negative association between activity level and body fatness is shown by relating body fat content to the ratio of total to resting energy expenditure (TEE/REE), a commonly used index of physical activity (150).

Intervention studies in which exercise was prescribed show that the weight loss achieved depends on the amount of exercise performed (151). Exercise is more likely to induce negative energy balance in subjects with a high capacity to oxidize fat (90) and when postexercise consumption of high-fat food is avoided (152,153). When the effect of a high-intensity intermittent training program was compared to that of an aerobic training program of moderate intensity (which raised energy expenditure more than twice as much), the former was found to cause a ninefold greater subcutaneous fat loss when expressed per MJ expended in training. In addition, the high intensity program induced a greater increase in the potential of skeletal muscle to oxidize fatty acids, as judged by muscle  $\beta$ -hydroxy-acylCoA dehydrogenase activity (87).

When fat loss becomes sufficient to decrease fat mobilization and oxidation (88,154), the ability of exercise to induce negative fat and energy balances declines. The effect of exercise in promoting fat oxidation is then offset by the decline of the fat mass, and a new steady state, at a lower degree of adiposity, is approached.

### **3 Synergistic Effect of High-Fat Diet and Sedentary Lifestyle**

Situations in which low physical activity is associated with the consumption of diets with a high fat content appear to be particularly conducive to the development of obesity. Indeed, these two conditions must prevail simultaneously for the prevalence of obesity to reach epidemic proportions. The reasons for this may be that

oxidizing fat at the rate at which it is consumed is problematic, when the contribution of muscle, the largest compartment in the body able to rapidly oxidize fatty acids, is low (Fig. 4). Indeed, the impact of running activity on the energy balance among ad libitum-fed mice is greater on mixed than on low-fat diets (88). Recent indirect calorimetry studies in men also reveal the significance of this linkage, not only because adjustment of fat oxidation to higher fat intake is prompter in physically active than in sedentary subjects (155), but also because this adjustment appears to be facilitated by concurrent physical activity (58).

#### 4 Impact of Hormones

Hormones can influence substrate oxidation by altering overall energy expenditure and the relative proportions of amino acids, glucose, and fatty acids being oxidized. The impact on body weight most clearly attributable to hormone-induced changes in energy expenditure occurs in cases of frank hypothyroidism or hyperthyroidism, whereas the effect of other hormones on adiposity is elicited primarily through their influence on the control of food intake and/or substrate metabolism.

In the case of amino acids and glucose, the effect of altered hormone levels or of altered responsiveness to their action can be offset by changes in the size of the protein and amino acid pools, and in glycogen stores and blood glucose levels, without affecting body composition in a readily detectable manner. Hormones that reduce fat oxidation, by inhibiting fat mobilization or by enhancing glucose oxidation, tend to raise the amount of body fat needed for fat oxidation to become commensurate with fat intake, and this can lead to changes in body composition and body weight that are clearly perceived and quantifiable.

Insulin is the main hormone curtailing fat oxidation, whereas growth hormone and catecholamines have the opposite effect. An important site for the expression of the antagonistic effects of these hormones is on the regulation of PDH, the enzyme catalyzing the irreversible step in the oxidation of carbohydrate. Thus, insulin promotes the activation of PDH, whereas increases in FFA and acetyl-CoA levels, elicited by catecholamines and growth hormone or by expansion of the adipose tissue mass, inhibit PDH (111). Interestingly, insulin and FFA levels are both elevated in obesity. The balance between the effects of elevated insulin and FFA levels on PDH activity would appear to have some importance, since body weight gain over several years tends to be less in obese subjects exhibiting insulin resistance (121).

The effect of  $\beta$ -adrenergic agonists tends to be more pronounced on lipid oxidation than on thermogenesis, whereas administration of  $\beta$ -blockers such as propranolol over a 2-week period resulted in a decrease in daily lipid oxidation three times greater than the decrease in energy expenditure, while carbohydrate oxidation was increased (63). Acute stimulation of sympathetic activity by exposing the lower body to negative pressure was found to induce a substantial increase in lipid oxidation, whereas energy expenditure was not altered (156). According to the RQ/FQ concept (114), a decrease in the use of fat relative to glucose is likely to increase food consumption, and a high RQ has indeed been a predictor for weight gain (60,61).

The situation is in reality much more complex than it appears by considering only the effects of hormones on peripheral fuel metabolism, notably because the neurosystems involved in the regulation of food intake are also influenced by insulin (157). Furthermore, hyperinsulinemia increases plasma noradrenaline (158) and muscle sympathetic nerve activity (159,160). Increases in sympathetic activity decrease energy intake and stimulate thermogenesis (8,9,161). However, since muscle sympathetic nerve activity represents only one component of sympathetic nervous system activity, it is not yet possible to generalize from this peripheral effect. In addition, high insulin levels in the central nervous system inhibit food intake (162), in part by inhibiting the fasting-related increase in the synthesis and release of neuropeptide Y (163), which is known to increase energy intake and to reduce thermogenesis (164). The hyperinsulinemia brought about by enlargement of the fat stores thus tends to restrain further weight gain through central effects (157). Conversely, the normalization of insulinemia achieved by weight reduction (165,166) may explain increasing resistance to further weight loss. Glucocorticoid hormones promote fat deposition, and they are in fact essential for the development of obesity in many genetically obese animals (167). As in the case of insulin, their action appears to be mediated by central nervous system as well as by peripheral effects (161). Growth hormone exerts the opposite influence; among other effects, it promotes fat oxidation relative to glucose oxidation (168). The balance of these various endocrine effects ultimately has to be judged by the impact they have on the size of the fat mass at which weight maintenance tends to occur.

#### 5 Impact of Drugs

Considerable efforts have been made to develop drugs that induce body weight loss, either by increasing energy

expenditure or by curtailing food intake. At present, most of the commonly used weight-reducing drugs act through their anorectic effects. When food intake is not restricted, the effectiveness of thermogenic stimuli for weight reduction depends on food intake not increasing enough to compensate for the drug-induced increase in energy expenditure. The phenomena regulating food intake thus remain an essential component in any rationale by which the impact of increases in energy expenditure in eliciting weight reduction is to be explained. The ultimate issue in explaining the weight-reducing influences of drugs (as well as of exercise) is why food intake regulation did not elicit an increase in food intake commensurate with the increase in energy expenditure. Since the RQ must on average be below the FQ to achieve weight reduction (49), weight-reducing drugs could be selected for their ability to help in achieving this condition, rather than merely for increasing energy expenditure.

#### **E Daily Substrate Oxidation Patterns in Lean and Obese Individuals**

Fat oxidation after an overnight fast is higher in obese than in lean subjects, in part owing to higher BMR and in part to lower RQ (154). The negative correlation between RQ and adiposity reflects the influence of the adipose tissue mass in raising FFA levels and in promoting fat relative to glucose oxidation. However, one should also allow for the fact that obese subjects often tend to consume diets with a higher fat content (89, 146,147) which could contribute to their relatively low postabsorptive RQ. Whatever the case may be, the average 24-hr RQ is equal to the diet's FQ in weight-stable subjects, be they lean or obese. If one assumes that the lower postabsorptive RQ observed in obese individuals is not imputable to a difference in the macronutrient composition of their diet, one would have to predict that the RQ would be higher in obese than in normal subjects during some periods of the day. This issue remains to be explored.

#### **F Substrate Oxidation and Predisposition to Obesity**

Most individuals reach a state of approximate weight maintenance in which the average composition of the fuels mix they oxidize matches the nutrient distribution in their diets. A rate of fat accumulation resulting in a gain of 1 kg of adipose tissue in a year represents a retention of only ~1% of the energy consumed, making

it difficult to detect differences in fuel oxidation under normal conditions. Nevertheless, under rigorously standardized conditions, it was found that subjects tending to have high 24-hr RQ, i.e., those tending to burn more glucose but less fat, were at a higher risk of gaining weight during subsequent years (60,61). The view that difficulty in burning as much fat as is consumed is an important factor in promoting obesity is further supported by the fact that adjustment of fat oxidation to increased fat intake occurs more slowly in obese than in lean subjects (25), placing them at greater risk for weight gain. Furthermore it was found that a low skeletal muscle oxidative capacity is associated with increased adiposity (169) and that skeletal muscle fatty acid utilization was reduced in women displaying visceral obesity (170).

Since adjustment of fuel oxidation to intake is achieved in lean and in obese subjects, once the fat mass has reached the size needed for fat oxidation to be commensurate with fat intake, it is necessary to compare postobese individuals to lean controls to identify possible differences in metabolic regulation. Such studies show daily fat oxidation measured by indirect calorimetry to be lower in the postobese subjects (55,171, 172). Furthermore, fat oxidation rises more slowly in postobese subjects than in lean individuals in response to an increase in dietary fat content (173,174). It thus appears that individuals predisposed to obesity are characterized by a reduced fat oxidation when they are tested in a postobese state. In formerly obese long-distance runners tested after a 39.5-kg weight loss, epinephrine stimulated adipose tissue lipolysis was much less than in runners who had never experienced problems with body weight control (175).

#### **G Interactions Between Genetic and Environmental Factors**

The powerful role of inheritance on obesity has long been recognized (176). However, the great increase in the prevalence of obesity in industrialized countries (177), in populations whose gene pool has been relatively constant, shows that environmental factors also assume considerable importance. These facts can be reconciled by recognizing that some genotypes are more affected than others when exposed to environmental factors that influence substrate oxidation and balances. The genotype-environment interactions have been investigated by subjecting monozygotic twins to well-defined nutritional and exercise conditions, and by comparing within-pair to between-pair responses. Such

studies suggest that heredity is a significant determinant of changes in body weight, energy expenditure, and body fatness induced by training (178,179) or overfeeding (180–182). The observation that weight gain was greatest in subjects predisposed to obesity (because at least one of their parents was overweight) and consuming diets with a relatively high fat content (183) supports the view that genetic traits affecting the regulation of glucose versus fat oxidation influence the risk for developing obesity.

## V CONCLUSIONS

When access to foods is unrestricted, stability of body weight is achieved in spite of differences in energy expenditure, whether these are due to differences in resting metabolic rates, in metabolic efficiency, or in physical activity. Since energy expenditure is not markedly affected by variations in food intake in man, maintenance of energy balance is overwhelmingly determined by the factors controlling food intake. Adjustment of the composition of the substrate mix oxidized to the macronutrient distribution in the diet is crucial in enabling control of food intake to occur in a manner bringing about short-term corrections in food consumption that sustain long-term weight stability. In individuals in whom fat oxidation tends to be low relative to glucose oxidation, substantial expansion of the adipose tissue mass is often necessary before this weight stability is reached.

## Skeletal Muscle and Obesity

**David E. Kelley**

University of Pittsburgh, Pittsburgh, Pennsylvania, U.S.A.

**Len Storlien**

University of Wollongong, Wollongong, New South Wales, Australia, and AstraZeneca, Mölndal, Sweden

### I INTRODUCTION

In obesity, there is increased nonadipose tissue as well as increased adiposity. The increase of nonadipose tissue entails an increase in skeletal muscle mass. Recent data indicate that obesity affects not only the quantity, but also the “quality” of skeletal muscle, and this will be one area of focus for this chapter. One manifestation of a change in the composition of skeletal muscle in obesity is an increased lipid content within and around muscle fibers. How this occurs is an important question. Altered composition of skeletal muscle may arise only as a consequence of having become obese, reflecting the general increase in adiposity in multiple organs. Yet, there are data that strongly suggest that changes in the physiology and biochemistry of skeletal muscle in obesity dispose to an accumulation of lipid within muscle. Indeed, these changes in muscle in fuel partitioning of lipid, between oxidation and storage of fat calories, may contribute to the pathogenesis of obesity and precede its development. This hypothesis could be of central importance to our understanding of this chronic disease and therefore will be carefully considered in this chapter.

A related theme of the chapter will be that skeletal muscle insulin resistance, a well-recognized metabolic complication of obesity, entails perturbations not only of glucose but also in fatty acid metabolism. In meta-

bolic health, skeletal muscle physiology is characterized by the capacity to utilize either lipid or carbohydrate fuels, and to effectively transition between these fuels. We will review recent findings that indicate that in obesity, skeletal muscle manifests a loss of the capacity for transition between lipid and carbohydrate fuels. This inflexibility in fuel selection by skeletal muscle, as well as differences in fuel partitioning, is a key pathophysiological characteristic that contributes to an altered composition of muscle in obesity and to the insulin resistance of muscle.

### II NONINVASIVE STUDIES OF SKELETAL MUSCLE COMPOSITION IN OBESITY

#### A Skeletal Muscle Quantity

Adipose tissue mass is certainly increased in obesity, and contributes substantially to increased weight. However, body composition analyses also suggest that there is an increased amount of nonadipose tissue components in obesity, including increased skeletal muscle mass. Two-compartment methods for estimating body composition, such as dual-energy x-ray absorptiometry (DXA) or underwater weighing, indicate that fat-free mass is increased in obesity. Part of the increase in fat-

free mass in obesity is represented by greater muscle mass than is present in lean individuals, otherwise paired for age and sex. Using DEXA in a region-specific manner, an increase of skeletal muscle can be shown in the extremities (1). Equally, Landin et al. (2) examined lean and obese middle-aged men and women using a method to detect total body potassium, a classic method of body composition that determines tissue mass apart from adipose tissue, due to the low potassium content of fat cells. Total body potassium, calculated from the natural isotope  $K^{40}$  determined in a whole-body counter, was higher in obese men and obese women than in their lean counterparts, indicative of increased skeletal muscle mass. In general, obese individuals with a body mass index (BMI) ranging from 35 to 40 kg/m<sup>2</sup> and weighing ~100 kg have ~5 kg more fat-free mass than do lean subjects with a BMI of 25 and weighing ~70 kg. In addition, Ross et al. (3) compared total and regional lean tissue distribution in obese men and women using magnetic resonance imaging. It was found, not unexpectedly, that obese women have significantly less total lean tissue than obese men. This difference was observed regardless of which body segment (head and arms, abdomen and torso, hip and pelvic region, and legs) was evaluated.

## **B Skeletal Muscle Quality—Imaging of Fat and Lean Compartments**

While quantitative muscle mass may be higher in obesity, a considerable body of literature has accumulated that shows that qualitatively this muscle mass is quite different in obesity with one of the features being different levels and localization of fats. Both computed tomography and magnetic resonance imaging are appropriate and sensitive tools for investigations of such issues (4).

### **1 Computed Tomography**

Computed tomography (CT) is a powerful *in vivo* imaging technique of growing sophistication [see (5) for a recent review of the technique]. CT is particularly effective at distinguishing between water and lipid and this is because the attenuation values measured by CT reflect the chemical composition of tissue. Using water as a reference value [set to 0 Hounsfield units (HU)], adipose tissue imaged by CT has a strongly negative attenuation value, generally ranging from -200 to -1 Hounsfield units. Thus, for example, a finding of lower attenuation in skeletal muscle in obesity is indicative of increased fat deposition within muscle, and recent

chemical phantom studies by Goodpaster et al. (5) have confirmed the relationship between lipid content and CT attenuation values.

During the past decade, a substantial body of data has emerged that indicate that the tissue composition of skeletal muscle differs between obese and nonobese individuals. Moreover, in obese individuals who undergo weight loss, the tissue composition of muscle can change. The differences in skeletal muscle composition between lean and obese individuals can be demonstrated both at the whole-organ level, using novel regional methods for body composition that have emerged in the past decade, and at the cellular level, using methods of microscopy and biochemistry. What is perhaps the most compelling finding is that skeletal muscle composition is a strong determinant of insulin resistance in obesity.

One of the earlier studies in this area was from the Kelley laboratory using CT of the thigh for regional analysis of skeletal muscle composition (6). In that study, and as later reaffirmed by Simoneau (7) and then Goodpaster et al. (1), in obesity there is increased cross-sectional area of skeletal muscle compared to lean individuals. These studies also reaffirmed the concept that women have less muscle mass than men, even when matched for degree of obesity. However, the more novel finding from these studies was that the "quality" of skeletal muscle is altered in obesity. In obesity, the CT attenuation value (expressed as Hounsfield units) of skeletal muscle is lower than in lean individuals, as shown in Figure 1. It is of interest that following weight loss the density of skeletal muscle increases and approaches the range of values found in lean individuals (8). This change in muscle reflects the fact that not only the quantity of muscle mass, but also its composition, is altered during periods of weight gain and weight loss. Reduced attenuation values for skeletal muscle are associated with aging and with gender, with lower values in older individuals and among women (9). The questions that arise therefore are what is being revealed by the reduced attenuation value of skeletal muscle, and why is this related to insulin resistance. As discussed below, muscle lipid content is a strong determinant of the CT attenuation values, and likely accounts for the association between CT attenuation values and insulin sensitivity and aspects of physical performance.

*In situ* imaging of skeletal muscle, as obtained by CT imaging, provides data concerning the impact of obesity on muscle structure that is not readily revealed by more classic two-compartment models, such as underwater weighing or DXA. To employ a two-compartment analysis, these approaches need to assume a constant density

**Figure 1** Shown in the upper and lower panels are histograms of the distributions of skeletal muscle attenuation values, in Hounsfield units, measured by computed tomography imaging of the mid thigh skeletal muscle. The dark shaded bars for muscle from a lean subject represent the normal distribution (95% confidence levels established in a group of lean, healthy volunteers). In muscle from the obese subject, the distribution of attenuation values is shifted to the left, and just approximately half of the pixels are within the normal range.

for fat-free mass. In situ imaging modalities have revealed some of the limitations of this assumption with respect to obesity.

There is an important physiological significance to the altered composition of skeletal muscle as revealed by CT imaging. Across several studies it has been found that the altered composition of skeletal muscle in obesity, as reflected in the lower CT attenuation values, is a correlate of the severity of insulin resistance (1,7,10). This association between muscle density and insulin sensitivity is at least partially independent of the ad-

verse effect of visceral adiposity to aggravate insulin resistance, a point to which we will return. Also, muscle attenuation values correlate to maximal aerobic capacity in young and middle-aged adults and with muscle performance in older individuals. In the Health ABC Study, a longitudinal study of the effects of aging on body composition and functional status, muscle strength and fatigue was correlated with muscle density, as revealed by CT attenuation values, after adjusting for the amount of muscle area (9).

## 2 Magnetic Resonance Imaging of Skeletal Muscle Lipid Content

A limitation of the computed tomography method is that the spatial resolution is not sufficient to fully distinguish between lipid contained within, and that present outside, myocytes. Areas of adipose tissue that are large enough to form a CT pixel can be identified as adipose tissue based on a negative attenuation value whereas a smaller deposit, not filling an entire pixel, might not meet attenuation characteristics to be imaged as adipose tissue. Another imaging approach, one that does seem to have a capability for distinguishing between intramyocyte and extramyocyte lipid, is magnetic resonance spectroscopy (MRS). Using MRS, and more specifically, using MRS to exploit fairly subtle chemical shift differences in these two lipid depots, it is possible to identify peaks that correspond to the methylene carbon of triglyceride from intra- and extramyocyte triglyceride (11). The extramyocyte triglyceride is contained within adipocytes within muscle, while the intramyocyte triglyceride is located within muscle fibers. Intramyocyte triglyceride is increased in obesity and is correlated with the severity of insulin resistance (12). Increases of intramyocyte triglyceride have been found in nonobese, first-degree relatives of individuals with type 2 diabetes mellitus and to relate to insulin resistance in this condition (13). The data suggest that the regional deposition of fat within skeletal muscle may be an early body composition abnormality in relation to insulin resistance, obesity, and type 2 diabetes rather than arising only as a late complication of excess adiposity.

The biochemical mechanisms that might contribute to the increased partitioning of fatty acids into muscle triglyceride are discussed later in this chapter. The fact that lipid accumulation can be seen relatively early in the development of insulin resistance adds to the concept that perturbed lipid metabolism by skeletal muscle may have a pivotal role in the development of obesity and its comorbidities.

### C Regional Adipose Tissue Distribution Adjacent to Skeletal Muscle

There is another aspect of muscle composition, from the whole-organ perspective, that has been learned from the application of regional CT imaging, and this concerns the distribution of adipose tissue outside skeletal muscle. There can be substantial subcutaneous adipose tissue located near muscle, and this is especially true with respect to the lower extremities. In general, and as opposed to depots such as visceral adipose tissue, adipose tissue located in the extremities has been regarded as relatively benign with respect to insulin resistance. However, recent studies suggest that this perspective needs to be modified to account for adipose tissue distribution, or sublocations. In the lower extremities, the majority of adipose tissue is in a subcutaneous location, above the muscle fascia. In CT imaging of the mid thigh, the fascial plane formed by the *fascia lata* can be discerned and it has been found that adipose tissue located beneath the *fascia lata* is significantly correlated with insulin sensitivity (negatively). In contrast, the much greater depot located above this fascia is not significantly related to insulin sensitivity in either men or women (14).

The mechanisms that account for the association of subfascial AT but not subcutaneous AT with IR are not well understood. At this juncture, only speculations can be made. Potential factors might be related to effects of fatty acids released by adipocytes adjacent to muscle, or it is also possible that in a paracrine manner, there are secreted products of this depot of adipocytes (e.g., cytokines) that influence insulin action within the adjacent skeletal muscle.

## III MICROSCOPIC STUDIES OF SKELETAL MUSCLE FIBERS IN OBESITY

### A Lipid Content in Muscle Fibers

Another approach to the study of lipid content within skeletal muscle is to directly examine tissue obtained by muscle biopsy. A number of studies have used muscle obtained by percutaneous biopsy of the vastus lateralis. Pan et al. (15) used this method and extracted lipid from the biopsy samples. Triglyceride was greater in skeletal muscle in obesity and was related to the severity of insulin resistance. However, even with careful removal of visibly identifiable adipose tissue, a potential limitation of performing lipid extraction from muscle biopsy samples is that the respective contributions of intra- and extramyocyte triglyceride cannot be determined. Direct

visualization of muscle fibers using microscopy can circumvent this issue (16).

In situ staining of neutral lipid with Oil Red O has been used to not only to ascertain that lipid droplets are contained within muscle fibers, but by the use of contemporary computer-assisted image analyses, this method can be used to obtain quantitative assessments. Several ultrastructural investigations of human skeletal muscle have shown that lipid droplets account for ~1% of cell volume within muscle cells in lean, healthy individuals. For instance, the volume percentage occupied by lipid in skeletal muscle of women represents values ranging from 0.5% to 0.7% depending on the fiber type investigated (17). Goodpaster et al. (18) observed that the volume of lipid droplets in skeletal muscle is increased in obesity and type 2 diabetes mellitus. In that study, the approximate volume within myocytes occupied by lipid droplets was 1.5% in lean volunteers, 3–4% in obesity, and slightly greater yet in type 2 diabetes mellitus. Also, following weight loss, the microscopic analysis of muscle tissue revealed less triglyceride, as would be consistent with the data from CT imaging of skeletal muscle.

In another study using light microscopy and the Oil Red O method, it was noted that not only the volume, but also the cellular distribution, of lipid droplets may differ in muscle from obese compared to lean individuals (19). In muscle from obese volunteers, the size of the lipid droplets did not appear to differ from those observed in muscle from nonobese individuals; simply, the muscle from obese individuals had more lipid droplets. However, in muscle from obese individuals, a higher proportion of lipid droplets appeared to be located more centrally within the muscle fiber (19). Additional research with higher resolution microscopy (e.g., electron microscopy) might be useful to further address the relation between lipid droplets and mitochondria and whether this is perturbed in muscle from obese individuals. It might be speculated that a more central location of lipid droplets within myocytes sequesters lipid, rendering it less likely to be utilized for energy. Certainly trained athletes have higher levels of intramyocellular triglyceride (20). That they are not insulin resistant may reflect both the increased mitochondrial density and possibly the distribution and relationship of the lipid droplets to those mitochondria (i.e., increased ability to utilize the fats).

### B Interaction of Muscle Fiber Type and Lipid Content in Obesity

One of the striking features that can be noted when examining the Oil Red O staining patterns in skeletal

muscle, especially human skeletal muscle, is that there is considerable heterogeneity between muscle fibers in the amount of lipid staining. This heterogeneity is related to muscle fiber type. It is well known, based on prior work with rat skeletal muscle, that muscle fiber types differ in their respective content of lipid (21–23). In general, type 1, or slow-twitch, oxidative (endurance) fibers contain greater lipid than type 2 fibers, and within the type 2 fibers, fast-twitch oxidative (sprint) fibers contain more lipid than do fast-twitch glycolytic (intermediate) fibers. Therefore, the question arises whether the increase in muscle triglyceride content in human obesity reflects an interdependence upon difference in muscle fiber type that might occur with obesity. To address this issue, He et al. (24) performed single-fiber analyses, in which serial sections of a muscle biopsy sample were stained for muscle lipid content (Oil Red O staining), muscle fiber type, muscle oxidative enzyme activity, and muscle glycolytic enzyme activity, as shown in Figure 2.

By serially measuring these characteristics for each muscle fiber, an overall profile for each fiber type could be ascertained. In the study by He et al. (24), vastus lateralis muscle from lean, obese, and obese type 2 diabetic men and women were examined. Lipid content was noted to be highest in type 1 fibers and lowest in type 2b fibers, with an intermediate value in type 2a fibers.

This pattern was observed in all three groups of subjects, but skeletal muscle from obese and type 2 diabetic individuals was found to have increased lipid content regardless of fiber type. In each fiber type, muscle from obese individuals had greater lipid content than lean individuals, and this was also found for individuals with type 2 diabetes mellitus.

An additional and equally important finding from the study by He et al. (24) was that skeletal muscle from obese individuals and from those with type 2 diabetes mellitus had a reduced oxidative enzyme activity, as determined by standard histochemical methods. As would be expected, type 1 fibers had the highest oxidative enzyme activity, followed in order by types 2a and 2b. Within each fiber type, oxidative enzyme activity was lower in individuals with obesity and with type 2 diabetes mellitus. The ratio of oxidative enzyme activity to lipid content was also examined. In lean individuals, this ratio was relatively consistent across fiber types, despite substantial differences between fiber types in content of lipid and oxidative enzyme activities. In muscle from obese or type 2 diabetic individuals, the ratio of lipid content to oxidative capacity was also relatively consistent across fiber types, but this ratio differed markedly from that found in lean individuals. The physiological meaning of this proportionality is

**Figure 2** Skeletal muscle, biopsied from vastus lateralis muscle, is shown stained for fiber type (ATPase), lipid content (Oil Red O), oxidative enzyme capacity (SDH), and glycolytic enzyme activity (GPDH). A biopsy from a lean volunteer and one from an obese volunteer are shown. The cryosections from muscle are stained in serial order so that these respective characteristics can be assessed within single fibers.

uncertain, though it might be speculated that a homeostatic balance between fuel stores and capacity for oxidative metabolism is present in lean individuals. If this is so, then the pattern in the muscle of individuals with obesity and type 2 diabetes mellitus suggests that lipid storage is increased out of proportion to the capacity of these myocytes for substrate oxidation.

### C Relation of Obesity to Muscle Fiber Type Distribution, Size, and Capillary Density

There have been several important studies that address whether the patterns of fiber type distribution differ in obesity and whether this is related to the pathogenesis of insulin resistance. It is commonly thought that type I muscle fibers in humans are better endowed for substrate oxidation than type II fibers. Reflecting this concept, it has been proposed that fiber type composition of skeletal muscle, in which type II fibers predominate, would be a determinant of obesity due to the lower substrate oxidation potential of this fiber type. In the testing of this hypothesis, conflicting results have been obtained.

A number of studies have reported that individuals with a high percentage of total body fat exhibit a low percentage of type 1 fibers in the vastus lateralis muscle (25–27). Wade et al. (26), on the basis of a rather small group of men ( $N=11$ ), suggested that at least 40% ( $r=-.65$ ) of the variability in fatness was related to variation in fiber type 1 proportion of vastus lateralis muscle. Similar results were obtained by Helge et al. (27), who also showed that a measure of trunk fat (central adiposity), obtained by DXA, was well related to % type 1 fibers ( $r=-.58$ ,  $P<.01$ ,  $n=21$ ). A more modest correlation coefficient ( $r=-.32$ ;  $P<.01$ ) was reported between the fiber type 1 proportion of vastus lateralis muscle and percent body fat in the study of Lillioja et al. (25) that involved 23 Caucasians and 41 Pima Indian nondiabetic men.

On the other hand, Krotkiewski et al. (28) have shown an absence of significant relationship between the proportion of type 1 fibers and obesity. It is possible that the significant relationships previously found could have been confounded by physical fitness of the subjects, which was not controlled.

The true relation between muscle fiber type and obesity should then be determined when level of fitness is controlled. Even here, however, the results are not entirely consistent. Simoneau and Bouchard (29) did not find a significant relationship between the proportion of type 1 muscle fibers and the amount of subcutaneous fat. That study examined a large cohort of women

and of men with substantial differences in subcutaneous fat content, but who were paired (within gender) on the basis of  $\text{VO}_2$  max expressed per kg body weight. In that study, there was a lack of difference in the proportion of type 1 muscle fibers between lean and obese individuals. In contrast, Segal et al. (30) found a significantly higher proportion of type 2b fibers in vastus lateralis muscle of obese individuals (29% vs. 17%) among lean and obese subjects paired on the basis of fat-free mass and  $\text{VO}_2$  max (30). Since it is the type 2b fibers that are glycolytic and have such limited capacity to utilize lipid for energy, it may be that this elevation as a percentage of total fibers is the critical factor. However, as we will come to below, fiber proportionality may be less relevant than oxidative capacity.

On another relevant aspect of muscle morphology, two studies from Krotkiewski et al. (28,31) have reported significant and positive correlation (with an  $r$  of  $\sim .4$ ) between total body fat and type 1 or type 2 muscle fiber areas. These results also indicate larger muscle fibers in obesity, and thus fit nicely with the results described previously indicating elevated fat-free mass in obese subjects.

The number of capillaries surrounding muscle fibers may also play an important role in substrate and hormone delivery, and therefore in determining insulin resistance. A reduced capillary density of muscle has been described in obesity. Krotkiewski et al. (31) have reported significant and negative correlations between fasting insulin level (indicative of insulin resistance) and the number of capillaries per area of type 1 ( $r=-.80$ ) or type 2a ( $r=-.62$ ) skeletal muscle fibers in human. Lillioja et al. (25) confirmed that observation using a direct measure of insulin action (the hyperinsulinemic, euglycemic clamp), although the relationship was less striking. As reviewed by Björntorp (32), if a reduced capillarity of skeletal muscle is a common phenotype of obesity, then a limited transfer of insulin from the capillaries to interstitial space and the surface of myocytes could affect the kinetics of insulin action in obesity. Substantial support for this concept has been obtained. The kinetics of insulin action in skeletal muscle is slower in obesity, and this has been largely attributed to slower transcapillary diffusion of insulin more than to a reduced rate of postbinding cellular signaling.

Finally, muscle's capacity for oxidative metabolism, and particularly to utilize fat, may decline with age. While the weight of evidence suggests no major change in proportion between type 1 and type 2 fibers with age (see, e.g., 33), there is one report in an Australian population of an age-related increase in type 2b ( $r=.45$ ,

$P=.01$ ) at the expense of type 2a fibers (34). In that study, both BMI and waist circumference were positively related to the percentage of type 2b fibers ( $r=.44$  and  $.49$ , respectively, both  $P=.01$ ). Interestingly, infants of age  $<2$  years were found to have extremely low levels of type 2b fibers ( $\sim 6\%$  vs.  $20+\%$  in adults). In contrast, a comparison with a young adult population of obesity-prone Pima Indians showed this latter group to have a much higher (approximately double) percentage of type 2b fibers than would have been predicted from the regression line of age versus % type 2b for the Australian subjects. From these studies, it seems clear that fiber type changes over the life span to forms with less oxidative capacity and less able to burn fat for fuel. In addition, there may be genetic predisposition either to higher proportions of type 2b fibers at birth, or to an increased rate of transition to type 2b fibers, with age. It is not clear whether an active or sedentary lifestyle contributes to the rate of change with aging, but certainly a relatively intense exercise program can shift the proportion of type 2b toward type 2a fiber (20). This may suggest that habitual exercise will help to maintain skeletal muscle capacity for fat utilization across the life span, a suggestion that has recently received experimental support (35).

#### IV BIOCHEMISTRY AND MOLECULAR BIOLOGY OF SKELETAL MUSCLE IN OBESITY

##### A Oxidative and Glycolytic Enzyme Profiles

Though the concept that fiber type distribution per se denotes metabolic capacity of skeletal muscle for insulin sensitivity and substrate oxidation has been a useful perspective, it is not entirely sufficient. Previous studies involving microphotometric determinations (36), ultrastructural investigations (37), or microbiochemical activity determinations in dissected single fibers (38) have shown that large variation exists in the metabolic profile within each fiber type of human skeletal muscle. Although the studies do report higher average mitochondrial enzyme activities or volume density in type 1 than in type 2a or type 2b fibers,  $> 50\%$  of type 1 fibers have aerobic-oxidative enzyme activities that are similar to type 2 fibers (36,37). Accordingly, it is important to distinguish between muscle enzyme capacities for substrate oxidation and muscle fiber type per se. Skeletal muscles with given enzyme activity levels may exhibit large differences in fiber type distribution, or vice versa (39). Rather than solely examining fiber type proportions, another, arguably better description of the

metabolic potential of skeletal muscle would be to directly determine muscle enzyme activities.

One strategy for determining the activity of muscle enzymes is to select key marker enzymes, chosen because they regulate diverse metabolic pathways and catalyze rate-controlling reactions for distinct, critical pathways of substrate utilization. Simoneau's laboratory carried out a number of such studies by assaying a panel of key enzymes. These included key regulatory enzymes of glycolysis (PFK, HK), glycogenolysis (PHOS), aerobic oxidative metabolism (CS), oxidative phosphorylation (COX), fatty acid oxidation (CPT, HADH), and anaerobic regeneration of ATP (CK). The rationale for assaying maximal activity of regulatory enzymes, as previously justified (40), is based on conventional Michaelis-Menten kinetics. The biochemical methodology most commonly used has been to determine maximal activity ( $V_{max}$ ) of each enzyme chosen for the metabolic profile. The activities of enzymes catalyzing nonequilibrium reactions (i.e., regulatory enzymes) provide a semiquantitative index of both maximal metabolic flux and fuel utilization. Activities of enzymes catalyzing reactions close to equilibrium provide only qualitative information about the importance of particular metabolic pathways and the principal fuels supporting activity (41). Importantly, and what is most pertinent to a consideration of substrate metabolism in obesity, is that the influence of maximal enzyme activity may be greatest at substrate concentrations below the  $K_m$  of the enzyme (40), and these are the conditions which prevail during daily living.

In these studies, Simoneau and Kelley and others found that the activities of several marker enzymes of oxidative and glycolytic capacity were altered in obesity. Citrate synthase (CS), an enzyme of the TCA cycle activity and a strong marker of oxidative capacity, was shown to be negatively correlated with visceral obesity ( $r=-.51$ ,  $P<.05$ ) (42). This was confirmed in an entirely different population (Pima Indians) both for central adiposity and for % total body fat ( $r=-.43$ ,  $P<.01$ ) (43). Conversely, CS activity was positively correlated with rates of lipid oxidation across the leg during fasting conditions and positively correlated with both whole-body insulin action and rates of glucose uptake during insulin stimulated conditions (7,44). These data indicate that oxidative capacity, as exemplified by CS activity, influences both postabsorptive utilization of FFA and insulin sensitivity. Conversely, glycolytic potential of muscle, as reflected by activity of phosphofructokinase (PFK), a regulatory enzyme in the glycolytic pathway, is increased in individuals with visceral obesity. In particular, the ratio of PFK/CS activity is a strong

marker of insulin resistance. Also, creatine kinase (CK), a cytosolic enzyme that catalyzes a key step in anaerobic regeneration of ATP, is increased in proportion to obesity and insulin resistance. Taken together, this pattern of enzyme activity indicates that insulin-resistant muscle is disposed toward anaerobic and glycolytic generation of energy. Our interpretation of the enzyme and metabolic data is that obesity adversely affects substrate metabolism by skeletal muscle during both basal and insulin-stimulated conditions.

In a recently published study, Sun et al. (45) examined whether the glycolytic and oxidative enzyme characteristics of vastus lateralis skeletal muscle and fiber type proportions in this muscle predicted the response to a 100-day supervised overeating protocol carried out in identical twins. The proportion of type 1 fibers correlated inversely with the overfeeding (1000 kcal/d, 6 days per week) induced weight gain, while the proportion of type 2a fibers correlated in a positive manner with the induced change in weight (45). This would suggest that muscle with a higher capacity for fat oxidation (type 1 compared to type 2a) might protect against weight gain in the setting of sustained positive energy balance. In further support, these investigators found the ratio between oxidative to glycolytic enzyme activities was an equally strong correlate. These data suggest the key role that skeletal muscle oxidative enzyme capacity might have in protecting against, or, conversely, increasing, the risk for obesity in an environment of access to high energy intake and reduced physical activity, as prevails in modern society, and stresses the need for future research of longer periods of observation.

## **B Capacity for Fatty Acid Oxidation**

Several clinical investigations suggest that the capacity for lipid oxidation is reduced in human skeletal muscle. Ferraro et al. (46) found that skeletal muscle lipoprotein lipase activity was decreased in obesity and that this was related to a decreased reliance on fat oxidation, as measured in a whole-body calorimetry chamber. Zurlo et al. (47), using a similar approach, found that marker enzymes of the beta-oxidation pathway are reduced in obesity. Simoneau (48) found reduced activity of CPT in skeletal muscle in obesity. The reduction in skeletal muscle CPT activity was of approximately the same proportion as the decrease in activity of other marker enzymes of mitochondria, such as citrate synthase for the TCA cycle and cytochrome C oxidase of the electron transport chain. This suggests a decrease in mitochon-

dria number or function, or both. Interestingly, following weight loss the subjects in the study by Simoneau (48) did not have improvement in the capacity for fat oxidation as measured by activities of CPT, CS, and cytochrome C oxidase. In that same study, an increased content of cytosolic fatty acid binding protein was found in obesity, with an additional gender-related effect of higher concentrations in women. However, other groups have found diminished content of cytosolic fatty acid-binding protein in skeletal muscle in obese individuals with type 2 diabetes (49).

Another line of investigation into the capacity of skeletal muscle for lipid oxidation concerns malonyl CoA. Although skeletal muscle has a relatively limited capacity for *de novo* lipogenesis, it does synthesize malonyl CoA. Ruderman and colleagues (50) have found that muscle content of malonyl CoA in rodents increases in response to insulin and glucose, and can be increased in insulin resistance and following denervation. Similar studies by Winder and colleagues (51) indicate that increased muscle glucose metabolism in skeletal muscle of the rat leads to an increased malonyl CoA concentration. This is potentially germane to the capacity for lipid oxidation because an increase in malonyl CoA can inhibit CPT I, the muscle isoform of which is particularly sensitive to inhibition by malonyl CoA (52). Several groups have studied the regulation of acetyl CoA carboxylase (ACC), the enzyme responsible for synthesizing malonyl CoA from carbohydrate (53,54). The thrust of this line of investigation is that conditions may prevail in obesity and glucose intolerance, as well as inactivity, for accumulation of malonyl CoA in skeletal muscle and thus lead to allosteric inhibition of CPT I and, consequently, an inhibition of lipid oxidation. Certainly, prolonged inhibition of CPT1 has been shown to increase intramyocellular triglyceride in studies on rodents (55). Then, excess triglyceride or FFA in muscle might lead to increased long chain acyl-CoA concentrations (56–58), which in turn might lead to further insulin resistance. We will return to this issue.

Still another line of inquiry concerns uncoupling proteins. Uncoupling proteins are postulated to influence thermogenesis, as is well supported by the role of UCP 1 in brown adipose tissue and suggested for homologs UCP 2 and 3. These findings have potential implications for the pathogenesis of obesity. Nordfors et al. (59) reported decreased expression of UCP 2 in skeletal muscle of human obese subjects. However, Simoneau et al. (60) found increased protein content UCP 2 in human skeletal muscle from obese individuals,

and examined the potential relation to energy expenditure and substrate oxidation, as well as to insulin resistance, which is common in obesity. Skeletal muscle UCP 2 content was significantly higher in obesity and was positively correlated with %FM ( $r = .60$ ;  $P < .05$ ). However, UCP 2 content in muscle was not correlated with basal energy expenditure ( $r = .03$ ;  $P = .93$ ), nor with insulin stimulated rates of glucose metabolism Rd ( $r = -.21$ ;  $P = .47$ ) (60). There was a significant correlation between muscle UCP 2 and patterns of macronutrient substrate oxidation within skeletal muscle, such increased UCP 2 was associated with higher fasting values of leg RQ ( $r = .57$ ;  $P < .05$ ), suggesting that UCP 2 may help to regulate nutrient partitioning within muscle and favor carbohydrate oxidation. Several lines of evidence suggest that UCP 3 expression is related to fatty acid availability (61).

### C Structural and Storage Lipid Subtypes and Lipid Signaling in Obesity

Lipids play a role in muscle metabolism not only as an energy source. As with all tissues of the body they are the major structural components of plasma and organelle membranes and act as potent metabolic intermediates in cellular signaling with their actions strongly dependent on the fatty acid subtypes involved. The fatty acid composition of structural and storage lipid in skeletal muscle is influenced both by genetic predisposition and by environment (particularly dietary fatty acid profile).

There is now considerable evidence linking obesity and skeletal muscle insulin resistance to the fatty acid composition of both phospholipid, the major membrane structural lipid (15,62,63) and myocellular storage triglyceride (64). These studies show that an increased proportion of saturated fatty acids in both lipid compartments relate directly and positively to impaired insulin action and to various measures of regional and total increased adiposity. A number of mechanisms have been postulated. Increased saturation of membrane lipids should decrease membrane fluidity, leakiness to ions and protons and hence decrease metabolic rate (see 65). Interestingly, increased membrane unsaturation improves intrinsic activity of ion transporters thus providing the conditions, in concert, to allow maintenance of ion homeostasis (66). Equally, it has been demonstrated that beta-adrenergic receptor affinity is decreased with dietary treatment emphasizing saturated fat intake (67), which is also consistent with decreased metabolic rate.

The indirect effects on energy balance via modulation of insulin action by lipid intermediates is likely to involve a complex series of cellular metabolic interactions which, pleasingly, the data are now beginning to clarify. Briefly, saturated fatty acids like palmitate specifically inhibit PKB/Akt activation and, concomitantly, insulin-stimulated glucose uptake in primary myocyte cultures (68). Equally, PKB activation has been shown to inhibit insulin stimulation of glycogen synthase kinase-3, thus impairing cellular capacity for glycogen synthesis (69,70). Both of these observations are likely to involve ceramide production; ceramide is a sphingolipid derivative of palmitate, being the condensation product of serine and palmitoylCoA. Ceramides are on the synthetic pathway for, and are also formed from the breakdown of, sphingomyelins. Sphingomyelin concentrations in adipose tissue and plasma have been shown to be positively related to obesity (71,72). Cytokines like tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) increase breakdown of sphingomyelins. Interestingly, salicylates (aspirin is acetylsalicylate) inhibit sphingomyelin-generated ceramide production and high doses have been shown to reduce obesity and improve insulin action (73,74) although other mechanisms are also likely to be important in explaining this observation.

Additional mechanisms of fatty acid modulation of muscle lipid metabolism are likely to come via influences on the sterol regulatory element-binding proteins (SREBPs). Activation particularly of SREBP1c induces a number of enzymes in the pathways of de novo fatty acid synthesis and through to triglyceride formation (see 75). It has recently been shown that while palmitate slightly induces SREBP1 expression in cell systems, more unsaturated fatty acids are powerfully inhibitory (76). Equally, it has been shown that diacylglycerol (DAG) accumulation, from an increase in fatty acyl-CoA availability, specifically from palmitate impairs insulin-stimulated glucose uptake in primary myocyte cultures (68). DAGs activate a number of isoforms of protein kinase C (PKC), and it is likely that a mechanism linking DAG accumulation from palmitate to impaired insulin action involves the known PKC inhibition of glucose transporter translocation. Palmitate is the major end product of endogenous lipogenesis via the fatty acid synthase cascade. In this regard it is interesting that mice with absent or reduced fatty acid synthase activity (knockout or cerulenin-treated) are lean and resistant to high-fat feeding-induced obesity (77). While the contribution of endogenous lipogenesis to the total fatty acid pool in humans is a matter of

controversy, it is now clear that saturated fatty acids play both a direct and indirect role in a range of skeletal muscle metabolic processes that will combine to predispose obesity.

## **V CLINICAL INVESTIGATIONS OF FATTY ACID METABOLISM BY SKELETAL MUSCLE IN OBESITY**

### **A Postabsorptive Patterns of Fatty Acid Use by Skeletal Muscle**

Skeletal muscle can oxidize either lipid or carbohydrate to yield energy. During postabsorptive conditions, as occur after an overnight fast, skeletal muscle predominantly relies on lipid oxidation. This is reflected in a respiratory quotient (RQ) across the forearm in lean individuals of approximately 0.71 to 0.82 (78–80). There is also a high rate of extraction of plasma FFA by skeletal muscle during fasting conditions, of ~40% (79). Oxidation of plasma FFA taken up by muscle, if these were to be completely oxidized, would account for nearly 80% of resting oxygen consumption by muscle. Thus, it is clear that skeletal muscle can have an important role in systemic patterns of fatty acid utilization, especially during postabsorptive metabolism.

In obesity, skeletal muscle has an increased content of triglyceride, as was emphasized in the preceding section. Accordingly, it is important to inquire as to the mechanisms that could account for increased skeletal muscle lipid deposition in obesity. Rates of *de novo* lipogenesis are low within skeletal muscle (81). Accordingly, skeletal muscle accretion of triglyceride in obesity would seem to arise as a consequence of an imbalance between the “importation” of plasma fatty acids and rates of fatty acid oxidation. Such a putative imbalance might result from increased fatty acid uptake, perhaps driven by increased plasma concentrations of fatty acids. Recent work from Boden and coworkers (82) has provided strong support for this possibility. In healthy young volunteers, they increased FFA levels by a combination of intralipid and heparin during a prolonged hyperinsulinemic, euglycemic clamp. They then measured both insulin action and accumulation of intramyocellular triglyceride by NMR spectroscopy. Even within 3–4 hr there was significant accumulation of intramyocellular triglyceride which related significantly to both the magnitude of elevation of the plasma FFA levels and, importantly, to the FFA-induced insulin resistance (82). Alternatively (or additionally), the excess accumulation of skeletal muscle triglyceride in obesity might arise from diminished rates of fat oxidation. Given the normal high reliance of skeletal muscle on lipid oxidation

during postabsorptive conditions, it would seem logical to inquire whether any defect in lipid oxidation in obesity is evident in this physiological context.

During the past decade and more, a number of studies have begun to address whether patterns of lipid utilization by skeletal muscle differ in obese compared to nonobese individuals. Ravussin and colleagues found that obesity is associated with an impaired capacity for oxidation of fat calories (46,83). These studies included data which suggest that higher values for RQ predict weight gain over several subsequent years (83). Two of the principal areas of investigation of the Kelley laboratory, especially in those studies carried out in collaboration with the late Jean-Aime Simoneau, have been to examine whether skeletal muscle capacity for lipid oxidation is reduced in obesity and whether there is a link between fasting patterns of muscle FFA utilization and insulin resistance.

An initial study in these directions, by Colberg et al. (44) was carried out in healthy young women who had a range of body mass index from 19 to 39 kg/m<sup>2</sup>. A key finding was that postabsorptive rates of FFA utilization by muscle were diminished in relation to visceral obesity. Women with increased visceral fat had neither lower plasma FFA nor lower rates for systemic appearance of FFA, yet manifested a reduced rate of plasma FFA uptake across the leg. The study also provided initial data that defects of lipid utilization by skeletal muscle and defects of insulin-stimulated glucose utilization might occur together. This was suggested by the correlation between fasting rates of lipid oxidation in muscle and insulin-stimulated rates of glucose storage in muscle ( $r = .61$ ,  $P < .05$ ).

### **B Metabolic Inflexibility of Substrate Utilization by Skeletal Muscle in Obesity**

Based on the findings from that initial study by Colberg (44) and similar data from other investigators (84), Kelley and Simoneau undertook a larger clinical investigation involving both men and women, and involving a weight loss intervention among the obese individuals (10). The first objective was to examine fasting patterns of lipid metabolism in order to test the hypothesis that reliance on lipid oxidation is reduced in obesity. The second objective was to determine whether fasting patterns of lipid metabolism were associated with the phenotype of insulin resistance in obesity. A close corollary to this was to assess how fasting patterns of lipid metabolism related to lipid metabolism during insulin-stimulated conditions. A third goal was to assess the impact of weight loss. The effects of weight loss are described in the subsequent section.

Volunteers for this study were approximately 60 healthy young adults. One-third of the group was lean. The rest were overweight or obese with BMIs  $> 25 \text{ kg/m}^2$  and ranging to an upper limit of 40. Leg balance measurements (product of arteriovenous differences and blood flow) for glucose and FFA uptake (based on the fractional extraction of  $[9, 10 \text{ }^3\text{H}]$  oleate) were carried out during fasting and insulin-stimulated conditions. Also, indirect calorimetry across the leg was performed to estimate substrate oxidation during fasting and insulin-stimulated conditions. The constant infusion of labeled oleate permitted measurement of uptake of plasma FFA across the leg despite the negative net balance of plasma FFA that occurs during postabsorptive conditions. Muscle tissue was obtained by percutaneous biopsy of the *vastus lateralis* muscle. Following baseline studies, the obese volunteers entered a weight loss intervention.

During fasting conditions, there was robust fractional extraction (FEX) of labeled FFA across the leg, of  $\sim 40\%$ , indicative of the uptake of plasma FFA by leg tissues. The FEX was similar in lean and obese subjects and was approximately 10- to 15-fold higher during fasting conditions than corresponding FEX for glucose. Rates of FFA uptake across the leg were similar in lean and obese subjects. However, despite similar rates of FFA uptake across the leg, rates of fat oxidation across the leg during fasting conditions were less in obese compared to lean subjects ( $P < .01$ ). During fasting conditions, obese subjects had an elevated leg RQ ( $0.90 \pm 0.01$  vs.  $0.83 \pm 0.02$  in lean controls;  $P < .01$ ). The RQ values across the leg in obesity denoted a reduced reliance on lipid oxidation, such that only a third of energy production was accounted for by fat oxidation while nearly twice that proportion was found in muscle of lean volunteers. In both lean and obese volunteers, the fasting rates of fatty acid uptake across the leg were greater than the fasting rates of lipid oxidation, indicating a modest net surplus of fatty acid uptake, as has been well described in animal studies (22,23). These rates of "net storage" of fatty acids were greater in obesity. Thus, a paradigm suggested by these findings is that in obesity, skeletal muscle accrues triglyceride owing to a reduced rate of lipid oxidation in the face of rates of fatty acid uptake that are equivalent to those of lean individuals.

A further key objective of the study of Kelley et al. (10) was to address the potential relation between insulin-resistant glucose metabolism and patterns of fatty acid uptake and oxidation during both fasting and insulin-stimulated conditions. Considering all subjects, lean and obese, a decreased reliance on lipid oxidation during fasting conditions was associated with

resistance to insulin stimulation of glucose metabolism, as shown in Figure 3. Fasting values for leg RQ were negatively correlated with insulin sensitivity ( $r = -0.57$ ,  $P < .001$ ). Thus, in addition to group differences in fasting leg RQ, there was significant correlation between the individual variation in the severity of obesity-related insulin resistance and fasting patterns of glucose and lipid oxidation in leg tissues. This observation extends our perceptions of what constitutes the phenotype of skeletal muscle insulin resistance since it reveals metabolic defects beyond those of insulin-stimulated metabolism. Thus, the phenotype of skeletal muscle insulin resistance in obesity appears to entail a broader concept of a organ system poorly performing its homeostatic function of substrate utilization. This concept may be central to understanding the role of skeletal muscle in the pathogenesis of obesity and obesity-related comorbid conditions, such as type 2 diabetes mellitus.

The hypothesis that insulin resistance is associated with decreased fasting fatty acid oxidation is a novel reformulation of the concept that perturbed skeletal muscle fatty acid metabolism may contribute to skeletal

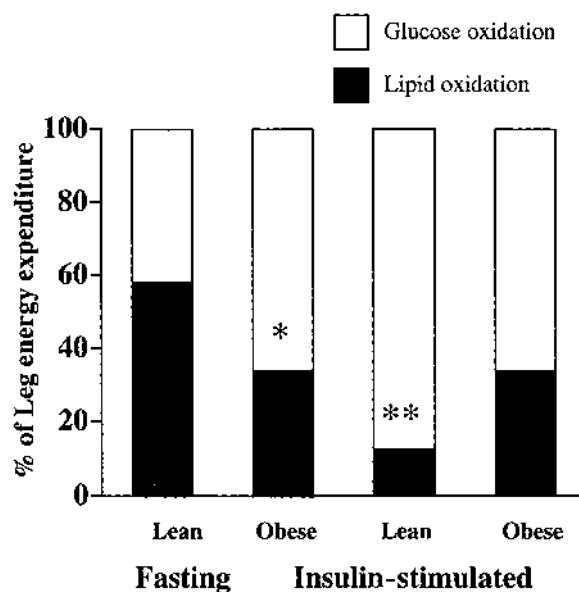

**Figure 3** Values for the respiratory quotient across the leg, during fasting conditions, measured by arteriovenous differences for oxygen and carbon dioxide in lean and obese volunteers are plotted against the respective values for insulin-stimulated rates of glucose utilization, measured using the glucose clamp method. There was a significant negative correlation between these variables. Individuals with a low value for leg RQ during fasting conditions, signifying a greater reliance on fat oxidation during fasting conditions, had a higher value for insulin sensitivity than did those individuals with a lower reliance on fat oxidation (as signified by the higher values for leg RQ) during fasting conditions.

muscle insulin resistance. The more classic concept of substrate competition in relation to insulin resistance is that “excessive” lipid oxidation reduces glucose utilization by skeletal muscle. It is appropriate to ask whether the finding that reduced fat oxidation during fasting conditions is related to insulin resistance of obesity is a contradiction to the “classic” Randle hypothesis of substrate competition and insulin resistance. Several recent studies indicate that glucose inhibits fat oxidation (85,86), a so-called reverse Randle cycle, which could be pertinent to the observation that insulin-resistant skeletal muscle in animal models of obesity has increased malonyl CoA (50) and that inhibition of ACC2 which decreases malonyl CoA results both in lower body fatness and improved glucose tolerance in mice (87).

In the study by Kelley et al. (10) insulin-stimulated conditions were examined, and therefore the role of fat oxidation during this physiological context was assessed in obesity and in relation to insulin-stimulated glucose metabolism. Under the stimulation of insulin, utilization of fatty acids by skeletal muscle is normally suppressed (88), though this can be disturbed by increased availability of plasma fatty acids (89,90). In lean subjects in these studies (10), infusion of insulin stimulated a significant increase in leg RQ ( $P < .001$ ), as shown in Figure 4, whereas in obese subjects, the insulin-stimulated values for leg RQ did not differ from fasting values of leg RQ. In lean subjects, infusion of insulin also stimulated a significant increase in rates of energy expenditure across the leg ( $P < .01$ ), whereas in obese subjects, rates of energy expenditure across the leg were unchanged compared to fasting conditions. Insulin-stimulated values for leg RQ were significantly greater in lean compared to obese subjects ( $0.99 \pm 0.03$  vs.  $0.91 \pm 0.02$ ;  $P < .01$ ). Thus, during insulin-stimulated conditions, obese subjects manifested a failure to suppress lipid oxidation and rates of lipid oxidation were unchanged from fasting conditions.

During insulin infusions, rates of leg lipid oxidation were negatively correlated to insulin sensitivity ( $r = -.45$ ,  $P < .001$ ); that is, greater lipid oxidation during insulin-stimulated conditions predicted insulin-resistant glucose metabolism, whereas during postabsorptive conditions, lower rates of lipid oxidation predicted insulin-resistant glucose metabolism. These findings are not disparate, but instead are interconnected pieces of the puzzle of how insulin resistance is manifest within skeletal muscle in obesity. The concept that links these two findings is one of metabolic flexibility as a component of insulin sensitivity in lean individuals and metabolic inflexibility as a component of insulin resistance in obesity. Obese subjects had less change in leg RQ in response to insulin infusion than did lean subjects.

**Figure 4** The contrast between a metabolic flexibility in the transition seen in lean subjects from a predominant oxidation of fat during fasting condition to predominant oxidation of carbohydrate during insulin-stimulated conditions is contrasted to a metabolic inflexibility in skeletal muscle in obese subjects, in whom there is little change in the relative proportions of carbohydrate and fat oxidation in the transitions from fasting to insulin-stimulated conditions, or vice versa.

Across the entire cohort, the amplitude of insulin-stimulated change in leg RQ ( $\Delta$  leg RQ: insulin-stimulated leg RQ – fasting leg RQ) correlated significantly with insulin-stimulated increases in glucose metabolism ( $r = .66$ ,  $P < .001$ ). This indicates responsiveness to insulin in modulation of leg RQ is related to capacity to respond to insulin stimulation of glucose uptake.

In obesity, the effect of insulin to suppress lipid oxidation was blunted, as has been previously reported (91, 92), and this clearly fits with the classic concept of fatty acid induced insulin resistance (93). Not only was incomplete suppression of lipid oxidation during insulin stimulation observed among the obese volunteers in this study, but rates of muscle lipid oxidation during insulin infusion were correlated with the severity of insulin-resistant glucose metabolism.

In summary, these observations do not indicate that fatty acid oxidation within insulin-resistant muscle is persistently “increased.” While insulin infusion did not suppress muscle lipid oxidation in obesity (compared to strong suppression in lean individuals), these rates of fat oxidation were unchanged from fasting conditions. During fasting conditions, rates of fat oxidation in skeletal muscle were lower in obese than in lean individuals.

Thus, in regard to the nature of substrate competition, muscle in obesity manifested a severe inflexibility in the modulation of fatty acid oxidation, with neither suppression by insulin infusion nor an appropriate enhancement in response to an overnight fast.

### C Effects of Weight Loss on Skeletal Muscle Lipid Metabolism

A critical issue is that of etiology, that is, whether impairments within the pathways of fatty acid utilization in skeletal muscle in obesity are primary defects or arise secondarily, after an individual has become obese. This is difficult to effectively address by cross-sectional comparisons of lean and obese subjects. A prospective clinical study has indicated that a decreased reliance on lipid oxidation is a risk factor for weight gain (83) and collateral analyses of skeletal muscle enzyme activities have implicated skeletal muscle in impaired lipid oxidation (46,47). A reduced reliance on lipid oxidation has also been identified as a risk factor for weight regain following weight loss (84,94,95). These data raise the possibility that a potential impairment in capacity for lipid oxidation might be a primary defect in obesity. Equally, weight loss can substantially improve insulin-resistant glucose metabolism in skeletal muscle (96) and at least aspects of muscle fat transport (97). This would seem to indicate that there may be also an acquired or secondary component of obesity-related insulin resistant glucose metabolism.

The third objective of the study by Kelley and colleagues (10), described earlier, was therefore to assess whether weight loss, undertaken by dietary restriction, could modulate patterns of skeletal muscle metabolism of fatty acids and how this would compare with the effect on glucose metabolism. Weight loss was achieved through restricted calorie intake and without changes in physical activity patterns or maximal aerobic capacity. A substantial weight loss was achieved ( $14.0 \pm 0.9$  kg, of which  $10.3 \pm 0.8$  kg was loss of fat mass) and then followed by a 1-month period of careful weight stabilization prior to re-assessments of metabolism. Fasting plasma insulin decreased ( $117 \pm 5$  vs.  $62 \pm 5$  pmol/L;  $P < .01$ ), as did plasma leptin (from  $39 \pm 2$  to  $21 \pm 2$  ng/mL in women and from  $16 \pm 3$  to  $6 \pm 2$  ng/mL in men). There were reductions in fasting plasma triglycerides, apoB, and total cholesterol. Systemic insulin-stimulated glucose metabolism increased following weight loss ( $5.9 \pm 0.4$  vs.  $7.5 \pm 0.5$  mg/kg FFM;  $P < .001$ ), and there was a twofold increase in arteriovenous differences for glucose following weight loss ( $P < .001$ ).

With respect to fasting patterns of skeletal muscle fatty acid metabolism, the effect of loss of weight was

relatively modest. Skeletal muscle oxidative enzyme activity was slightly diminished, and activity of CPT was unchanged (and remained lower than in lean subjects). Not unexpectedly (98,99), rates of resting energy expenditure measured by limb balance were lower following weight loss, and rates of fatty acid uptake were slightly reduced. Yet, the leg RQ was unchanged from pre-weight loss values; thus, reliance of skeletal muscle on fat oxidation during fasting conditions was not improved. The observation that weight loss had a lesser effect on fatty acid metabolism than on glucose metabolism raises the provocative question as to whether abnormal fatty acid metabolism by muscle is a primary rather than an acquired metabolic impairment in obesity or obesity-prone individuals. Persistent impairment of fatty acid metabolism has been previously reported following weight loss (84,94,95,100). These data would suggest that these defects could be primary impairments, leading to obesity rather than merely resulting from obesity. Furthermore, it is interesting to speculate on what might have happened had the intervention included aerobic exercise. In lean sedentary subjects, aerobic exercise training promotes an increase in oxidative enzyme capacity and this is accompanied by an increased rate of fatty acid oxidation during exercise conditions (40,101).

Two changes that did occur in muscle fatty acid metabolism following weight loss were that insulin infusion stimulated a significant rise in leg RQ (compared to fasting values) and a significant suppression of fat oxidation, and there was an overall increase in muscle attenuation values on CT imaging (indicating a loss of muscle fat). Furthermore, following weight loss, rates of fatty acid uptake during insulin-stimulated conditions were nearly equivalent to rates of fat oxidation, whereas the rate of fat oxidation had exceeded fatty acid uptake during insulin infusions prior to weight loss. This change in insulin-stimulated patterns of muscle fatty acid metabolism is indicative of more complete suppression of lipolysis of muscle triglyceride.

## VI INSULIN-RESISTANT GLUCOSE METABOLISM OF OBESITY

While the perspective of this chapter has been to give emphasis to the emerging concepts of altered fatty acid metabolism in skeletal muscle, it is also important to review the substantial body of data concerning insulin resistant glucose metabolism in obesity. In obesity, skeletal muscle typically manifests insulin resistance. This observation derived from seminal clinical investigations, conducted nearly three decades ago (102,103).

The insulin resistance of obesity seems to affect the pathway of glucose storage more severely than that of glucose oxidation (91,104,105). Recognition of this metabolic pattern in the insulin resistance of obesity has spurred a thorough examination of the insulin regulation of the glycogen synthesis pathway, with particular focus on the enzyme glycogen synthase, which is generally regarded as a rate-limiting step in glycogen synthesis (41). Obesity is associated with impairment in insulin activation, via dephosphorylation, of glycogen synthase (104), and the magnitude of this defect is correlated to the defect in nonoxidative glucose metabolism and overall systemic insulin resistance. Thus, these findings affirm the importance of impaired glycogen formation within muscle as a key process in the pathophysiology of insulin resistance in obesity.

In the past decade, several novel methods for studying proximal steps of glucose metabolism (i.e., glucose transport and phosphorylation) within skeletal muscle have been developed for clinical investigations and again NMR is important for imaging substrate concentrations within tissue. In addition, positron emission tomography (PET) is a region-specific imaging method that provides spatial mapping of metabolism. Both of these methods have been applied to the study of skeletal muscle insulin resistance. In a series of elegant studies, Shulman and colleagues (106–108) have used NMR to investigate skeletal muscle metabolism. By combining NMR with infusion of  $^{13}\text{C}$  glucose, these investigators have been able to quantify rates of insulin-stimulated glycogen formation in skeletal muscle, and have found that this metabolic pathway is profoundly disturbed in the insulin resistance of type 2 diabetes mellitus, and with the insulin resistance of obesity. This group has also used phosphorous NMR to study accretion of glucose-6-phosphate during insulin-stimulated conditions, as a means to study insulin regulation of glucose transport and phosphorylation. These studies indicate that in obesity, there is impairment of these proximal steps of glucose metabolism. A similar overall conclusion has been achieved using a limb balance approach combined with isotope tracers to separately study glucose transport and phosphorylation (109,110), though this method has not been used in obesity per se, but only in obesity complicated by type 2 diabetes mellitus. Dynamic PET imaging, combined with mathematical modeling of the tissue activity curves of the uptake of the tracer  $^{18}\text{F}$ -deoxy-glucose has revealed that in obesity there are potentially separate impediments of insulin activation of both glucose transport and phosphorylation (111,112). These findings from NMR, PET, and the forearm triple-tracer method indicate that glucose

transport and phosphorylation are rate-controlling sites of insulin action in skeletal muscle.

Among overweight individuals, the severity of insulin resistance is correlated with the degree of obesity, though in a nonlinear manner (113). In males, beyond a body fat content of  $\sim 30\%$ , the impairment of insulin sensitivity is not further aggravated by greater adiposity. Also in men, and to an even more pronounced extent in women, the relationship between obesity and insulin resistance is influenced by body fat distribution and is greater in proportion to upper body fat distribution (114).

The issue of body fat distribution as it relates to insulin-resistant glucose metabolism in skeletal muscle is a particularly interesting topic and can be extended beyond consideration of upper- versus lower-body fat distribution. As cited previously, fat deposition within muscle is a powerful marker of insulin resistance, and this component of fat distribution contributes to insulin resistance independently from overall adiposity (42). These results were paralleled by those of Pan et al. (15), who showed that skeletal muscle triglyceride concentrations and a measure of central adiposity were both strong, independent influences on whole-body insulin action in a nondiabetic group of adult Pima Indians. The negative effects of obesity to cause insulin resistance can be modulated by physical activity and training (as reviewed in 115) such that insulin resistance tends to be less severe among obese individuals with higher indices of aerobic power (116).

In the diet intervention study in obese men and women described earlier (10), an additional purpose was to examine whether the amount of weight loss or the amount of change within a specific aspect of regional fat determined the extent of improvement in insulin-resistant glucose metabolism in skeletal muscle. The average weight loss was 15% of baseline weight, and there were substantial and significant losses of fat mass, visceral adipose tissue (measured by cross-sectional CT imaging), and abdominal subcutaneous adiposity, as well as thigh subcutaneous adiposity (8). There was of course, individual variation in the amount of weight loss and of weight loss associated changes in the various components of regional adiposity, and as well, in the amount of change in insulin sensitivity of muscle glucose uptake. The amount of weight loss, or loss of fat mass (absolute or as a percentage), did not significantly correlate with the amount of improvement in insulin resistance. However, the percentage change in visceral adiposity did significantly correlate with the improvement in insulin resistance (8). This was the first clinical investigation to demonstrate a specific link between changes in insulin

sensitivity and changes in visceral adiposity, though earlier studies had shown a correlation with improved glucose tolerance. These findings add additional credence to the concept that the amount of visceral fat, although a relatively small proportion of total body adipose tissue mass, is nevertheless of special significance for muscle metabolism.

In recent studies carried out in 23 men and women with type 2 diabetes mellitus, using PET imaging to measure muscle insulin sensitivity of glucose metabolism, the level of insulin-suppressed fatty acids was found to be a strong determinant ( $r = -.81, P < .001$ ), and in turn, the level of insulin-suppressed fatty acids was found to be correlated with visceral adiposity but not with other depots of adipose tissue or fat mass. Thus, it will be crucial to continue to examine the link between muscle insulin resistance and visceral adiposity in order to advance our understanding of the metabolic complications of obesity.

## VII SUMMARY AND CONCLUSIONS

In summary, the composition and biochemistry of skeletal muscle are altered in obese as compared to nonobese individuals. These alterations dispose to a reduction in the role of skeletal muscle in oxidation of lipid calories and to a pattern of macronutrient partitioning that increases lipid storage within skeletal muscle and systemically. Such a key role for skeletal muscle in the pathogenesis of obesity is certainly consistent with the capacity which skeletal muscle has to utilize both carbohydrate and lipid fuels and with the major role which skeletal muscle can have in overall fuel balance. An important morphological characteristic of skeletal muscle in obesity is increased content of fat, particularly the intramyocellular component. Accretion of fat within muscle tissues appears to strongly correlate with insulin resistance. This fat accretion within muscle of obese individuals may not be simply a passive process, paralleling fat storage in other tissues. Instead, and of particular metabolic interest, is the emerging concept that biochemical characteristics of skeletal muscle in obese individuals dispose to fat accumulation in muscle and may contribute substantially to the development and maintenance of the obese state. These biochemical characteristics of muscle in obese individuals have long been recognized to include insulin resistance in pathways of glucose metabolism, and more recent studies indicate as well a reduced capacity for the utilization of fat calories. Again, it must be emphasized that a key feature of skeletal muscle in obesity is a marked inflexibility in modulation of fat utilization.

Further research is needed to define the stages at which these patterns emerge. Whether these factors exist prior to the onset of increased rates of weight gain and obesity or whether they occur in response to these changes has not been clearly delineated. An important area of investigation is to assess skeletal muscle characteristics in longitudinal studies, relating skeletal muscle characteristics (oxidative enzyme levels, fiber proportions, etc.) to subsequent development of obesity and stratified for levels of physical activity. Such studies should be possible on cohorts of individuals studied one to two decades ago and would increase enormously our understanding of the role of muscle morphology in the etiology of obesity.

The task at present is to more precisely define the nature of the defects within the pathways of fat metabolism, to discern the contribution of environmental and genetic influences, and to utilize these insights to develop effective treatment strategies. An effort to modify skeletal muscle of obese individuals so that its capacity for substrate utilization (and in particular, fat oxidation) is improved should be among the goals of treatment for obesity. Whether capacity for fat oxidation by muscle can be enhanced by pharmacological treatment is largely unknown, and though it is clear that nutritional and exercise interventions can improve insulin sensitivity of skeletal muscle in obese individuals, there remains much to be learned about optimal behavioral methods to attain this goal.

## ACKNOWLEDGMENTS

The authors would like foremost to acknowledge and remember the valuable contributions of Dr. Jean-Aimé Simoneau, who passed away in 1999. Dr. Simoneau was an insightful investigator of obesity and the role of skeletal muscle in the pathogenesis of obesity. This chapter is dedicated to his memory. We would also like to acknowledge the helpful comments of many colleagues, and the cooperation of the many research volunteers, without whom this knowledge could not have been gained.

## Nutrient Partitioning

**Samyah Shadid and Michael D. Jensen**

Mayo Clinic, Rochester, Minnesota, U.S.A.

### I INTRODUCTION

#### A General Considerations on Nutrient Partitioning

Nutrient partitioning can be defined as the process by which the organism selects fuels for storage (including protein synthesis) or oxidation. Understanding the regulation of energy balance and nutrient partitioning can potentially facilitate the treatment of obesity. Although the factors that lead to an imbalance between energy/fat intake and energy expenditure, and thus the development of obesity, remain incompletely understood, nutrient partitioning may be especially relevant to the development of obesity as it relates to the hypothesis of Flatt (1). The latter suggests that total food intake increases to meet carbohydrate needs. According to this theory, food intake is regulated, at least in part, to assure an adequate amount of carbohydrate. Consumption of a high-fat diet would require the intake of excess fat in order to satisfy carbohydrate needs and therefore lead to obesity under this scenario. The concept of a diet “relatively” deficient in carbohydrate becomes important in that dysregulation of substrate partitioning could potentially affect the body’s sense of what constitutes adequate carbohydrate intake. For example, if fat were preferentially shunted toward storage, more carbohydrate would be required to meet oxidative needs, thereby preventing sufficient repletion of glycogen stores. This process is proposed to generate signals that

stimulate appetite. Other examples where nutrient partitioning relates to obesity and body fat content include the stimulation of lean tissue synthesis at the expense of fat calories by androgens and growth hormone, and (presumably) the reverse of this process by deficiencies of these hormones.

A variety of physiological and cellular events play key roles in determining nutrient partitioning. After a general overview of these major determinants, the regulation of the major pathways of nutrient partitioning will be reviewed, followed by specific hormonal influences on each pathway. The net effects of the major nutrient partitioning hormones (insulin, growth hormone, testosterone and cortisol) on lipid, protein, and carbohydrate metabolism are summarized in Figures 1–3.

#### B Nutrient Partitioning and Exercise

When energy intake exceeds energy expenditure, the excess calories must be stored. Excess energy intake in sedentary, hormonally stable adults almost inevitably results in the expansion of adipose tissue triglyceride stores. Circumstances that promote lean tissue accretion, however, can allow excess energy to be stored as muscle and/or visceral proteins. The most common circumstance resulting in net lean tissue accretion with excess food intake is increased physical activity, usually in the form of resistance exercise training. The initiation of endurance exercise training in a previously sedentary

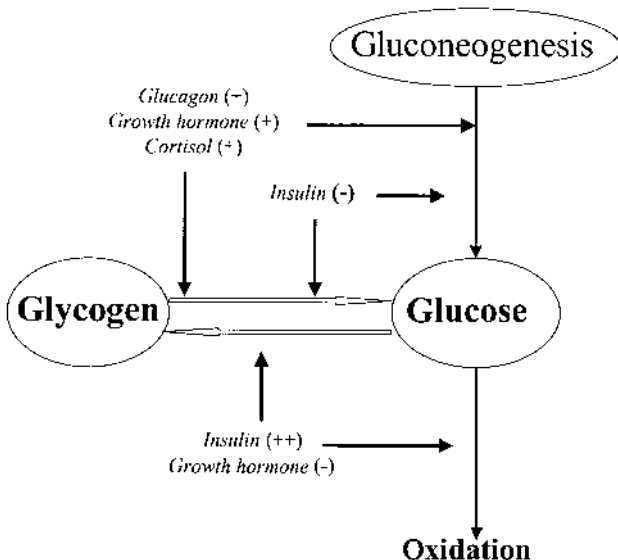

**Figure 1** Endocrine control of lipid metabolism. Only direct and noncontroversial effects are depicted.

individual can have similar, albeit less pronounced, effects on lean body mass. Finally, during the recovery from catabolic illness, repletion of lost body proteins is an important fate of excess energy.

Alterations in nutrient partitioning can also occur at a relatively stable weight. For example, the reduction in protein synthesis and increased fat accumulation with aging can be considered a form of nutrient partitioning. Whether the changes are driven solely by lesser physical activity or are aggravated by other (e.g., hormonal) fac-

**Figure 2** Endocrine control of glucose metabolism. Only direct and noncontroversial effects are depicted. Cortisol and growth hormone have additional effects to increase plasma glucose concentrations by inducing insulin resistance.

**Figure 3** Endocrine control of protein metabolism. Only direct and noncontroversial effects are depicted. The enhancement of protein synthesis by insulin is controversial. \*Proteolysis increases in acute hypercortisolemia, which, in chronic steroid excess, is controversial.

tors is not clear. In summary, ingested nutrients can be directed towards increasing body protein, increasing body fat, or, to a much lesser degree, expanding carbohydrate stores.

### C Endocrine Influences on Nutrient Partitioning

Endocrine disturbances have long been associated with either the development of obesity and/or the result of obesity. Examples include Cushing's syndrome, thyroid disorders, insulin resistance, and polycystic ovarian syndrome. In some cases, endocrine influences may alter fat content and body composition by altering nutrient management without markedly changing either energy intake or expenditure.

Another point of interest is body fat distribution, a determinant of obesity-induced morbidity that is as important as the absolute amount of body fat. Upper-body obesity, which usually connotes visceral obesity, is more strongly associated with insulin resistance, hypertension, coagulation abnormalities, dyslipidemia, and cardiovascular death than obesity per se. Lower-body obesity, in which fat preferentially accumulates in the gluteofemoral region, is less strongly associated with these health hazards.

### D Energy Expenditure and Metabolism

Nutrient partitioning could be accompanied or exaggerated by changes in energy expenditure. Human energy expenditure is usually broken down into three compo-

nents: basal metabolic rate (BMR), the thermic effect of food, and physical activity. Basal metabolic rate is determined primarily by lean body mass, and thus hormonal effects that increase lean tissue will increase BMR. The thermic effect of food is determined primarily by the amount of carbohydrate and protein ingested, but may be reduced in insulin-resistant states. Physical activity thermogenesis is a product of the mass of the body moved and the amount of movement. Hormonal effects on energy expenditure and substrate oxidation could theoretically influence either the amount of energy expended in one of these components or the mix of fuels oxidized. To the extent that hormones influence either energy expenditure or substrate oxidation these issues will be covered.

## II PROCESSING OF FUEL

The main sources of dietary energy are carbohydrates (4 kcal/g), proteins (4 kcal/g), fat (9 kcal/g), and alcohol (7 kcal/g). Alcohol will not be discussed. Fat, carbohydrates, and protein can serve functions in addition to fuel provision and the ultimate fate of these molecules depends on a variety of factors, among which hormonal influences are of importance.

### A Lipid Metabolism

Dietary triglycerides are transported in chylomicrons for storage or oxidation. Effective utilization of triglycerides requires the action of lipoprotein lipase (LPL), which is present on the capillary endothelium of many tissues. Adipose tissue and muscle are the major tissues responsible for triglyceride clearance by LPL-mediated fatty acid uptake. Very low density lipoprotein (VLDL), secreted by the liver, is the other major form of circulating triglyceride. The fatty acids in these triglycerides derive largely from plasma free fatty acids (FFA), as described below.

Fat stored in adipocytes is mobilized by the action of hormone-sensitive lipase (HSL), which hydrolyzes the triglyceride, resulting in the release of glycerol and FFA. Free fatty acids circulate bound to albumin, are present at relatively low concentrations (300–600  $\mu\text{mol/L}$  in the postabsorptive state) and turn over rapidly in the circulation (half-life of  $\sim 4$  min). Uptake of FFA can be for use as an oxidative substrate (heart, muscle, etc.) or for reesterification (e.g., in liver) and subsequent transport in VLDL particles. At rest, FFA release and uptake rates generally exceed fatty acid oxidation rates. Hepatic reesterification of FFA and secretion as VLDL

triglyceride can account for a portion of the FFA that are released in excess of fatty acid oxidation. It is thought that substantial portions of VLDL triglyceride fatty acids are re-stored in adipose tissue.

Under conditions of grossly excessive carbohydrate intake, glucose can be converted to fatty acids. This process is referred to as *de novo* lipogenesis, and is thought to take place primarily in the liver. It is energetically inefficient and accounts for a very small fraction of the fatty acids present in VLDL triglyceride under usual conditions.

The availability of FFA in the circulation drives fatty acid oxidation to a significant extent, as shown by the coordinate changes in fatty acid oxidation resulting from artificial elevation and lowering of plasma FFA concentrations. Some of the hormones that influence substrate partitioning may do so by in large part by altering FFA release from adipose tissue. For example, growth hormone stimulates lipolysis whereas insulin inhibits lipolysis, which in turn promotes and inhibits fatty acid oxidation. Fatty acid oxidation can also be regulated at other steps, however. It is possible for hormones to inhibit or stimulate fatty acid oxidation over and above their effects on FFA availability, thus sparing carbohydrate as an oxidative fuel. Altering the portion of fatty acids that enter reesterification pathways or altering fatty acid transport into mitochondria could modify fatty acid (and thus glucose) oxidation independent of circulating FFA availability.

#### 1 Regulation of Lipolysis

Because of the importance of FFA availability in determining substrate oxidation, a brief overview of adipose tissue lipolysis will be provided. Under overnight postabsorptive conditions, adipose tissue lipolysis is restrained by the prevailing insulinemia; pharmacological inhibition of insulin secretion using somatostatin results in an approximate doubling of FFA release rates. Physiological hyperinsulinemia is capable of suppressing FFA release rates by 80–90% from basal levels, and FFA concentrations by  $>90\%$ . Insulin-resistant obese individuals display greater maximal release of FFA during insulin withdrawal and lesser suppression of FFA during hyperinsulinemia. Catecholamines are also potent regulators of adipose tissue lipolysis. Epinephrine infusions can increase FFA release by three- to fourfold. This is similar to the stimulation of lipolysis that occurs during exercise. Catecholamines act through the stimulation of  $\beta$ -adrenergic receptors via a classic Gs-protein/cyclic AMP mechanism that activates HSL (2). Other hormonal regulators of lipolysis include

growth hormone and cortisol, although these are generally considered to be much less potent than insulin and catecholamines.

## B Carbohydrate Metabolism

Most dietary carbohydrate is converted into glucose before storage or oxidation. The liver is the only organ that stores carbohydrate as glycogen for eventual export as glucose. The regulation of hepatic glucose export is under exquisite control by a variety of hormones, although insulin and glucagon are considered the most potent acute regulators of glucose availability.

There is a limited capacity for glucose storage as glycogen, such that increasing carbohydrate intake beyond usual needs quickly leads to increased carbohydrate oxidation, with an attendant reduction in fat oxidation. Increasing carbohydrate intake in the face of unchanging fat intake will result in increased fat storage as glucose replaces fat as an oxidative fuel. Massive increases in carbohydrate intake can stimulate *de novo* lipogenesis, although the capacity for this appears quite limited in humans (see Sec. II.A).

Reductions in carbohydrate intake are accompanied by some degree of glycogen depletion and by shifts toward greater fat oxidation. If energy intake is less than energy expenditure, fatty acids from preexisting stores are oxidized, resulting in relatively good preservation of protein stores. The shifts in carbohydrate and fatty acid oxidation that take place with changes in carbohydrate intake appear to be primarily regulated by the changes in insulin secretion that accompany the dietary changes.

## C Protein Metabolism

Proteins include structural proteins, enzymes, nucleoproteins, oxygen-transporting proteins, contractile proteins, etc. The amino acids in these proteins are part of an interchangeable pool. The daily turnover of amino acids is substantially greater than the amount ingested as dietary protein; only a minor fraction of amino acids are oxidized or converted to glucose or fat.

Mechanical stimuli enhance skeletal muscle contractile protein synthesis, whereas hormonal and other factors determine the synthesis rates of many types of proteins. Given the tremendous variety of proteins in the body, many of which have specific regulatory pathways, this chapter will make only general reference to hormonal or metabolic regulation of protein metabolism.

## III ENDOCRINE CONTROL OF NUTRIENT PARTITIONING

### A Endocrine Control of Lipid Metabolism

#### 1 Insulin and Lipid Metabolism

Insulin is an anabolic hormone, which promotes glucose as the preferred substrate for oxidation, sparing amino acids and fatty acids for protein and triglyceride accretion. Fat sparing is achieved via both the suppression of lipolysis and the facilitation of adipose triglyceride uptake, likely by enhancing the synthesis of adipose tissue lipoprotein lipase. It is unclear whether insulin has independent effects on FFA transport into cells. An insulin-mediated decrease in plasma FFA concentrations directly affects nutrient partitioning and substrate utilization. It is of great quantitative importance to insulin's effects on peripheral glucose uptake and oxidation: the lack of FFA supply forces peripheral tissues to intensify their use of glucose as oxidative fuel (Sec. III.B.1). In the pathological event of ineffective suppression of lipolysis following meal ingestion, such as in insulin resistance states, more fat and less glucose will be oxidized. This is proposed to be a mechanism by which the insulin resistance of obesity increases fat oxidation, thereby allowing the individual to eventually balance fat oxidation and fat intake. This will be further discussed below.

Insulin regulation of adipose tissue lipolysis displays a regional variation. Leg adipose tissue lipolysis is readily suppressed by insulin (3), with upper-body subcutaneous and visceral adipose tissue FFA release being less well inhibited (3). This is true in both lean and obese humans (3,4). If regional adipose tissue fatty acid storage were equal in all adipose tissue beds, one would expect gradual expansion of lower body fat stores. Studies of leg and abdominal subcutaneous, and of visceral adipose tissue indicate that regional variations in fatty acid uptake are in the same direction as regional variations as FFA release (5). Thus, whether regional differences in insulin action contribute to differences in body fat distribution is unknown.

#### 2 Growth Hormone and Lipid Metabolism

The effects of GH on fuel partitioning are directed toward the use of fat as the preferred oxidative substrate. One of its main effects is, therefore, to increase FFA availability to peripheral tissues. However, its metabolic effects are biphasic: in the first ~90 min after secretion, a transient insulinlike effect is observed, characterized by accelerated glucose uptake and oxidation (6). Only after this effect has dissipated, GH adopts lipolytic and diabetogenic effects.

Regulation of fat metabolism is IGF-1 independent (7). GH stimulates fat mobilization, but in addition inhibits its uptake via the inhibition of adipose tissue LPL (8). This is reported to take place at a posttranslational level (8,9); an influence on LPL gene expression has not been consistently observed in vivo or in vitro (8,10). Whether GH affects skeletal muscle LPL is controversial (8,10,11).

Fatty acids are mobilized from adipose tissue via GH induced stimulation of HSL, of which the action, but not the production, is promoted (12). This is suggested to be mediated via increased adipocyte responsiveness to catecholamines (11,13); however, whether this is entirely responsible for the increased lipolysis is unclear.

In addition to increasing FA availability, GH directly enhances fat oxidation, at least in part, by stimulating the conversion of fatty acids to long chain acyl-CoA within responsive cells (14). This saturates the cells with fuel and thus decreases uptake of glucose (see Section II.B.2).

In clinical practice, the lipo-oxidative effect of GH is reflected in the increased and reduced fat mass in GH deficient and acromegalic patients, respectively. This can be reversed back to normal after treatment (7,15–17).

### 3 Testosterone and Lipid Metabolism

Testosterone has a major influence on fat metabolism. It affects fat distribution, fatty acid uptake and oxidation, and perhaps also lipolysis. This last may be related to synergistic effects with GH. These aspects have primarily been studied using testosterone supplementation in hypogonadal men and adolescents with delayed puberty, as well as by the artificial induction of testosterone deficiency in lean, healthy young men (18–20). The latter, achieved via the administration of a GnRH analog, diminishes rates of lipid oxidation and resting energy expenditure, but increases body fat mass. This suggests that testosterone-induced increases in fatty acid oxidation are not entirely due to the greater muscle mass. However, it is not clear to what extent these changes in fat oxidation result from direct effects on intracellular fatty acid trafficking versus from changes in FFA availability. Although testosterone increases adipocyte lipolytic responsiveness to catecholamines (norepinephrine, isoproterenol and forskolin), in both in vitro and some in vivo studies, basal lipolytic rates are influenced in neither (18,21,22). Fat deposition is greatly influenced by testosterone, among others via its inhibition of LPL (22).

### 4 Estrogens and Lipid Metabolism

The effects of estrogens on fuel partitioning are most noticeable in the quantity and distribution of body fat. During female puberty, the latter is redistributed toward gluteofemoral deposition, which is thought to be estrogen mediated. Despite maintaining substantially more body fat (average of 30% in nonobese women compared to 15% in nonobese men), women have less visceral fat, greater amounts of lower-body fat, and lower cardiac risk factors (e.g., serum lipids) than men do. This gender difference persists throughout the adult reproductive life but begins to reverse after menopause.

However, the direct effects of estrogens on adipose tissue dynamics have been incompletely studied. Whereas a possible effect of estrogens on triglyceride uptake does not appear to have been investigated, adipose tissue fuel export has, but with conflicting results. Estrogens have been reported to increase, to decrease, or not to change lipolysis, in both animal and human studies (2,23). The only direct intervention studies, however, show that transdermal estrogen decreases adipose tissue FFA release in postmenopausal women (24) and lowers plasma FFA concentrations in ovariectomized women (25).

Equally conflicting are the data concerning the influence of estrogen on the partitioning of fat and glucose toward oxidation. One group reported that combined estrogen/progesterone supplementation of postmenopausal women did not alter basal substrate oxidation (26) but that, after a mixed meal, carbohydrate oxidation increased at the expense of lipid oxidation. This change occurred only at 30–60 min after meal ingestion, and only in the group of women given oral estrogens. Transdermal estrogen administration resulted in an opposite, but nonsignificant, effect. Another study failed to find effects of transdermal estrogen treatment on substrate oxidation under basal, insulin clamp, or adrenergic stimulation conditions (24). In contrast, inhibition of estrogen synthesis in men with an aromatase inhibitor tended ( $P = .09$ ) to reduce basal lipid oxidation (27).

In summary, estrogens seem to alter body fat distribution and dynamics, but their exact influence remains unclear. Data on fat uptake are absent, and data on lipolysis are controversial. Nevertheless, estrogens seem to stimulate FFA release from adipose tissue and to increase lipid oxidation.

### 5 Glucocorticoids and Lipid Metabolism

The regulation of fat, glucose, and protein metabolism by glucocorticoids is characterized by a system that

sophisticatedly redistributes nutrients over the body, according to their biological priority in stress situations (see Section II.C.4). In fat metabolism this is reflected in a net whole body lipolytic effect, which occurs simultaneously with (perhaps localized) stimulation of LPL as long as small amounts of insulin are present (28–30). The net result is an increase in FFA concentrations and fat oxidation (31,32). However, the lipolytic effect of acute hypercortisolemia, which is a facilitating effect on catecholamine-induced lipolysis, is counteracted by concomitant insulin overproduction, so that FFA release remains very limited *in vivo*. It has been suggested that regional stimulation of LPL might contribute to redistribution of fat by cortisol, analogous to its role in protein metabolism. Fat may be broken down in one region but stored in another under conditions of excess glucocorticoid availability: while lipolysis supplies increased amounts of FFA to peripheral tissue, circulating triglycerides (VLDL and chylomicrons), derived from increased food intake, may be preferentially stored in truncal fat (see below).

The increased FFA supply stimulates fatty acid oxidation, as shown by both indirect calorimetric measurements (decrease in RQ) (28) and appearance of ketone bodies (33). Whether cortisol also increases fat oxidation via direct intracellular effects is unclear.

In chronic hypercortisolemia, there is a net increase in fat mass and body weight despite greater fat mobilization (34). It is not completely understood why this increased fat mass is also redistributed in the centripetal pattern, typical of Cushing's syndrome. However, there is evidence that the synthesis of enzymes responsible for adipocyte fatty acid uptake is differentially regulated by cortisol, possibly mediated by regional differences in expression and/or sensitivity of cortisol receptors.

## **B Endocrine Control of Carbohydrate Metabolism**

### **1 Influence of Insulin on Glucose Metabolism**

Insulin largely controls glucose uptake into most cells, and stimulates both glucose oxidation and glycogen storage; skeletal muscle is the predominant site of postprandial glucose disposal. Insulin also suppresses endogenous glucose production by inhibiting hepatic glycogenolysis and gluconeogenesis. Thus, insulin largely orchestrates the disposal of meal carbohydrate by simultaneously inhibiting endogenous glucose production and stimulating the uptake and oxidation/storage of blood glucose.

The concept that failure to suppress fatty acid concentrations in the face of hyperinsulinemia will impair

glucose disposal and oxidation has been confirmed. If the fall in FFA concentrations in response to hyperinsulinemia is prevented by infusing a lipid emulsion and heparin, glucose disposal and oxidation are not stimulated to the expected degree. In addition, normalizing the suppression of FFA in volunteers with type 2 diabetes (whose lipolysis is normally quite resistant to insulin) by administering acipimox, a drug with antilipolytic properties, markedly enhances insulin action with respect to glucose metabolism (35).

Insulin also promotes glucose oxidation and storage independent of its effects on substrate availability via direct action on intracellular events. Evidence for these effects has been provided by *in vivo* studies in which FFA concentrations have been maintained (via an intravenous lipid and heparin infusion) during hyperinsulinemic, euglycemic conditions. In these experiments, glucose uptake, storage, and oxidation increase above basal levels in response to insulin, although the rates do not equal those seen when FFA concentrations are allowed to fall normally (36). This response is clearly evident in skeletal muscle (36), but not in liver (37). These direct intracellular effects of insulin are mediated by a complex signaling cascade that regulates glucose transporter availability at the cell membrane, as well as the activity and synthesis of numerous enzymes. The details of this process are beyond the scope of this chapter.

### **2 Influence of Growth Hormone on Glucose Metabolism**

Although GH stimulates the use of fat as the preferred oxidative substrate, it also causes plasma glucose concentrations to rise, which cannot always be compensated for by increased insulin release (7,38). This is achieved in various ways. First, the stimulation of FFA availability and the direct stimulation of fat oxidation saturate the cell with energy molecules and thus decrease cellular uptake and oxidation of glucose (7); glucose that enters the cell is deposited as glycogen. In some tissues, GH directly inhibits glucose uptake independent of FFA concentrations (39). In addition, GH stimulates hepatic glucose production (7). As a result, in situations of both acute and prolonged excess, GH has a diabetogenic effect.

### **3 Influence of Testosterone on Glucose Metabolism**

The induction of hypogonadism in healthy men with GnRh analogs does not lead to evident changes in serum glucose levels or glucose availability. Insulin concentra-

tions do tend to increase. Of interest, testosterone treatment in adolescents with delayed puberty causes insulin stimulated oxidative and nonoxidative glucose disposal rates to decline (18). These effects could well be temporary, as is the insulin resistance of puberty, and may be related to increased competition from greater fatty acid oxidation. In obese men, who are known to have lower plasma testosterone levels, testosterone administration increases insulin-stimulated glucose disposal rates (40). Whether this is a direct or an indirect effect, perhaps relating to changes in fat distribution or adipose tissue function, is not clear.

#### 4 Influence of Estrogens on Glucose Metabolism

Estrogens have not been shown to influence glucose production or insulin-mediated glucose disposal in humans. Contrary to the decrease in glucose disposal found in ovariectomized rats and mice (41), insulin sensitivity in postmenopausal women is reported to be unchanged or even increased (41,42). Longitudinal studies of women going through menopause found unchanged glucose tolerance (43) and unchanged fasting glucose, but increased fasting plasma insulin concentrations (44). However, changes in fasting insulin in the perimenopausal time period are confounded by the changes in body fat and body fat distribution that commonly occur at this time of life (44). We conclude that the impact of estrogen on glucose metabolism in humans is too subtle to be clinically significant, if present at all.

#### 5 Influence of Glucocorticoids on Glucose Metabolism

During both acute and chronic hypercortisolemia, glucose levels are almost invariably reported to increase, which is only partially attenuated by simultaneously increasing insulin levels (28,45). This is a combined effect of a decrease in insulin stimulated glucose uptake and of glucose overproduction (14,28,33). The former might be due to the increased circulating FFA, and, in chronic corticosteroid exposure, perhaps also to changes in muscle fiber types (see below). As expected, whole-body glucose oxidation diminishes (28,29). Glucose overproduction can be in part attributed to increased gluconeogenesis, which is induced by the increased supply of amino acids (especially alanine) and glycerol, derived from protein and fat mobilization (14,45,46).

It is likely that the combination of increased circulating glucose and peripheral insulin resistance, again, is a reflection of fuel redistribution: peripheral organs are

forced to derive their energy from fat, saving glucose for usage in the brain. As the latter is unable to derive its energy from fat, its glucose uptake is practically insulin independent and can continue even during stress situations, during which energy use intensifies. Prolonged and/or extreme corticosteroid excess, however, can induce diabetes. The relative insulin deficiency of the diabetic state will further aggravate the protein catabolic effects of hypercortisolemia. Thus, the combination of corticosteroid excess and uncontrolled diabetes is particularly disadvantageous with respect to nutrient partitioning (47).

### C Endocrine Control of Protein Metabolism

#### 1 Insulin: Control of Protein Metabolism

The net lean tissue maintaining effect of insulin is achieved by the inhibition of proteolysis, and perhaps also by stimulating protein synthesis; the latter is somewhat controversial and is thought to occur via a direct stimulation of amino acid transport into cells, which should facilitate protein synthesis. The suppression of proteolysis reduces the release of amino acids from tissues into the circulation. In the context of a mixed meal (i.e., one providing protein as well as carbohydrate), the plasma amino acid concentrations increase as a consequence of gut delivery of amino acid into the circulation. Increased amino acid availability plays a role in stimulating protein synthesis. If insulin concentrations increase from the ingestion of pure carbohydrate or during intravenous glucose and insulin infusions, plasma amino acid concentrations and protein synthesis rates fall. Thus, the nutrient partitioning effects of insulin with respect to protein metabolism are strongly influenced by the nutrient content of the challenge.

Inherent regional and tissue differences in insulin action can potentially regulate regional nutrient partitioning. Skeletal muscle protein metabolism is affected differently by insulin than is splanchnic protein metabolism. Under overnight, postabsorptive conditions, when plasma insulin concentrations are at basal levels, skeletal muscle is a net exporter of amino acids (i.e., protein breakdown exceeds protein synthesis) whereas protein synthesis exceeds protein breakdown in the splanchnic bed (48). Increasing the plasma insulin concentration results in suppression of muscle protein breakdown without stimulating protein synthesis, but suppresses protein synthesis in the splanchnic bed without altering protein breakdown (48). The reduction in splanchnic protein synthesis in response to insulin may have been related to the fall in plasma amino acid

concentrations resulting from isolated hyperinsulinemia. Thus, partitioning of amino acids between skeletal muscle and nonskeletal muscle sources is at least partially regulated by insulin.

## 2 Growth Hormone: Control of Protein Metabolism

GH minimizes the use of amino acids for fuel but increases their utilization for protein synthesis. GH enhances the latter by increasing cellular amino acid uptake in synergism with insulin (14,49) and modulating DNA and RNA transcription. Synergistic effects with testosterone make this more pronounced in males than in females. GH influences on protein metabolism occur via IGF-1 (7,14), although the presence of both hormones together has a greater effect than each one separately (49). Whether GH additionally inhibits proteolysis is controversial. Although many studies show no effect of GH on proteolysis (50), 6-hr GH infusions in healthy volunteers showed GH to suppress net forearm alanine, phenylalanine, and leucine release (51,52). It is unknown whether this merely reflects a decreased amino acid efflux, secondary to their increased extraction from the circulation (52), or a true suppression of proteolysis. IGF-1 has been demonstrated to induce proteolysis in animal and human studies (49). GH decreases amino acid oxidation by ~20%, as shown by GH administration to GH deficient adults (52,53) and children (7).

## 3 Testosterone: Control of Protein Metabolism

Acute testosterone deficiency, induced by GnRH analogs, has been shown to decrease whole-body protein synthesis and proteolysis, resulting in a decrease in fat-free mass and muscle strength (19). Testosterone supplementation studies have confirmed these conclusions, except for the effects on proteolysis, which was found to decline under the influence of testosterone.

These studies consistently reported that testosterone administration or deficiency did not change amino acid oxidation rates or plasma amino acid concentrations. This suggests that testosterone amplifies muscle mass by enhancing intracellular partitioning of amino acids toward protein synthesis (especially in muscle) rather than by increasing amino acid uptake. The latter has been confirmed in amino acid tracer studies of testosterone administration in healthy young men (54). It should be noted, however, that these studies are conducted in fasted states and that, under physiological conditions, cellular amino acid availability and uptake are expected to increase due to postprandial fluctuations in other hormones such as insulin and GH.

## 4 Estrogens: Control of Protein Metabolism

The influence of estrogens on protein metabolism is controversial. Although there is no question that estrogen modulates the synthesis of selected hepatic, endometrial, and other proteins in humans (55), whole-body protein pools seem to be unaffected, which has been observed in studies administering estrogen to hypogonadal girls (55) and estrogen inhibitors (anastrozole) to young men (27). In both studies, amino acid turnover rates and amino acid oxidation were unchanged.

Apparently, estrogen affects selected protein pools without changing whole-body protein kinetics, perhaps because the tissues strongly affected account for a relatively minor fraction of total protein synthetic activity. Circulating amino acid availability does not seem to be affected by estrogens.

Of note, the estrogen inhibition in the Mauras et al. study (27) increased testosterone concentrations and decreased IGF by 18%, despite unchanged GH and IGFBP-3 concentrations. This contrasting effect on two strongly anabolic hormones, which is consistently confirmed in other studies, might blur direct measurable effects of estrogens in *in vivo* studies and creates yet another difficulty in the investigation of the fuel partitioning effects of estrogens. This is further complicated by the observation that GH production is stimulated by orally, but not transdermally, administered estrogens (26,56). Although the reason for this difference is not completely understood, it might influence the apparent effects of estrogen on several aspects of fuel partitioning.

## 5 Glucocorticoids: Control of Protein Metabolism

The well-established protein catabolic qualities of cortisol are far from random. Protein (but also fat and carbohydrate) supplies are mobilized, re-stored, and re-directed according to their biological priority in stress situations. Acute hypercortisolemia increases whole-body proteolysis (28,33,45) and concomitantly decreases whole-body protein synthesis (49). However, the production of some proteins, such as some hepatic proteins and some lymphocyte proteins, is selectively stimulated (57). Overall amino acid oxidation increases (28,58).

With chronic hypercortisolemia, whole-body protein synthesis has also been shown to decrease, whereas the effects on proteolysis are controversial (47,49). In addition, with prolonged hypercortisolemia, protein catabolism progressively outpaces protein synthesis (28,57), leading to the evident protein wasting in the skeletal

muscle and skin in Cushing's syndrome, which accentuates the characteristic centripetal fat redistribution.

Furthermore, over time structural changes can be observed in muscle. In addition to the above-mentioned atrophy, one study found that muscles in Cushing's syndrome may contain more type II<sub>b</sub> (32% vs. 12%) than type I fibers (30% vs. 55%) compared to control subjects (59). Type II<sub>b</sub> fibers have a lower glycogen synthase activity and fewer mitochondria and are therefore thought to be more insulin resistant. Interestingly, upper-body obese women display characteristics similar to those of women with Cushing's syndrome.

#### IV NUTRIENT PARTITIONING IN OBESITY

##### A General Considerations

Although the general principles of fuel partitioning are similar in obese and lean individuals, several changes in baseline endocrine physiology occur in obesity, particularly the visceral type. Although the insulin resistance is best known and studied, low GH concentrations, high or low testosterone concentrations (depending on the gender of the individual; see below), and a hyperactive hypothalamic-pituitary-adrenal axis have been observed in obesity.

None of the mechanisms has been elucidated. The many hypotheses formulated on these matters have been challenged by conflicting *in vitro* and *in vivo* observations. However, they seem likely to reflect adaptations of the body to a new environment of energy surplus, and one could well argue that the observed changes are part of a protective mechanism. Insulin resistance has been proposed as a way to limit weight gain (60), whereas the decline in GH is suggested to subdue the tendency for high FFA concentrations in central obesity, which might prevent further worsening of insulin resistance. These issues will be discussed in the following sections. The clinical relevance of this knowledge lies in a correct interpretation of lab findings in obese patients and in keeping otherwise abnormal results in perspective. Treatment aspects will not be covered.

##### 1 Insulin and Nutrient Partitioning in Obesity

Insulin resistance with respect to glucose and fatty acid metabolism is an exceedingly common feature of obesity, being more severe and more prevalent in upper-body/visceral obesity. As noted above, this insulin resistance with respect to adipose tissue (less stimulation of LPL synthesis, less suppression of lipolysis) would

theoretically act to make more lipid fuel available, thus displacing glucose as an oxidative substrate. If there is a sensing mechanism whereby the internal stimuli for energy intake are modulated by the availability of glucose, the reduced carbohydrate oxidation resulting from insulin resistance could serve to limit excess energy intake. In this regard, insulin resistance has been proposed as a mechanism to limit weight gain (60).

The development of type 2 diabetes in obese adults results in a host of nutrient partitioning changes. The relative insulin deficiency allows further excess mobilization of FFA from adipose tissue, which in theory would further depress glucose uptake and oxidation. The hyperglycemia itself, however, facilitates glucose uptake and oxidation independent of insulin, thereby limiting the extent to which fatty acid oxidation can increase. The loss of the restraining effect of insulin on skeletal muscle protein breakdown results in substantial losses of muscle in uncontrolled diabetes. In addition, glycosuria results in the nonoxidative loss of carbohydrate. This catabolic state with regard to adipose, muscle, and carbohydrate can be reversed with insulin administration or insulin secretagogues at the expense of weight gain. This weight gain could well be muscle tissue and repletion of glycogen (with its attendant water), with limited adipose accumulation. Thus, the energy deposition that occurs when uncontrolled diabetes is treated is an excellent example of nutrient partitioning into lean tissue.

In summary, insulin is involved to a major extent in virtually every aspect of nutrient partitioning. The primary issue that will face clinicians with respect to this hormone and obesity is the weight gain that attends insulin or insulin secretagogue therapy for uncontrolled type II diabetes.

##### 2 Growth Hormone and Nutrient Partitioning in Obesity

The role of GH in obesity is complex and somewhat controversial. Although primary growth hormone deficiency leads to centripetal adiposity, visceral obesity *per se* results in a secondary reduction in serum GH concentrations (61). However, we view this as an adaptation to the state of energy surplus.

The differences in the pathophysiology of the two conditions are exemplified by the different IGF-1 concentrations. IGF-1 is very low in primary GH deficiency, but may be normal, high, or somewhat reduced in obesity. In the last case, IGF-1 concentrations are usually only slightly lowered from normal. Moreover, a simultaneous change in the production of IGF-binding

proteins in central obesity (decreased IGFBP 1 and 2 vs. increased IGFBP 3) may result in high free, biologically active IGF-1 fractions, exceeding those in lean subjects (61). Therefore, IGF-dependent functions of GH, such as the growth ability of children, remain unchanged in obesity (61).

One could reasonably argue that reduced GH may dampen the tendency for high FFA concentrations in central obesity, thereby preventing further worsening of insulin resistance. Indeed, treatment of centrally obese adults with GH, while resulting in body fat loss, is almost uniformly associated with further increases in FFA and worsening glucose intolerance/insulin resistance.

The mechanisms behind this hypsomatotropinism in obesity have yet to be clarified. Reductions in spontaneous GH secretion (as much as 6% for each unit increase in BMI) and in the half-life of circulating GH have been reported (61). Moreover, the GH response to pharmacological (GHRH, L-dopa) and physiological stimuli, such as sleep, physical exercise, insulin-induced hypoglycemia, and corticosteroids, is impaired in adiposity (61).

Several theories have postulated explanations for the decreased GH concentrations, focusing on IGF-1, FFA, peripheral hormones, and the central nervous system. Increased plasma concentrations of FFA, IGF-1 and insulin are observed in obesity, all of which are known to provide negative feedback control on GH secretion and thus might contribute to the development of hypsomatotropinism. However, the quantitative importance of either of these feedback loops in mediating the alterations in GH dynamics in obesity is unknown. In addition, conflicting *in vitro* and *in vivo* evidence has challenged these and other theories, concentrating on leptin and the central nervous system (61).

### 3 Testosterone and Nutrient Partitioning in Obesity

Testosterone deficiency leads to visceral fat accumulation; however, analogously to GH, visceral obesity as a primary entity is also associated with lower free testosterone levels in men (62). As noted above, however, in women visceral obesity is associated with increased free testosterone (63). A satisfactory explanation for this paradox has yet to be found; in neither case is it clear whether this is based on a cause-and-effect relationship, or if so, whether the central fat accumulation leads to changed testosterone levels or vice versa. In both sexes, weight loss has been consistently found to reverse the abnormalities in testosterone levels (64–67). Several theories have postulated hormones such as

leptin and GH to mediate the observed changes. However, neither is compatible with the changes in testosterone levels in women (68,69), and each theory is met with many other counterarguments.

In conclusion, upper-body obesity is associated with reversible high testosterone levels in women but low levels in men. Though the latter relationship has been intensively investigated, insight in the mechanism remains poor, theories varying from direct cause-and-effect relationships to indirect effects involving leptin and GH.

### 4 Glucocorticoids and Nutrient Partitioning in Obesity

Visceral obesity shares many characteristics with Cushing's syndrome. Both conditions are associated with large abdominal subcutaneous fat cells with high lipolytic qualities, insulin resistance, hypertension, and even buccal fat accumulation (70,71). In addition, the changes in muscle fibers described in women with Cushing's syndrome were also found in upper-body obesity (59).

As neither of these is typical of lower-body obesity, it has been suggested that visceral adiposity might be associated with changes in the hypothalamus-pituitary-adrenal (HPA) axis or cortisol receptors. Indeed, one glucocorticoid receptor polymorphism is associated with visceral obesity (72), although it is unclear how common or physiologically relevant these types of gene polymorphisms are in upper body adiposity. The fact that the HPA axis, on the other hand, is closely intertwined with food intake, makes a role in the development or sustaining of visceral obesity more plausible. CRH is a potent anorexic peptide; the increased appetite, found in most types of hypercortisolemia, is thought to be mediated by feedback inhibition of corticosteroids on CRH release. In rodent models, CRH administration reduces the body weight threshold for food hoarding behavior (73).

Therefore, obesity has been proposed to be a CRH-deficient state. However, the changes in HPA axis found in obesity, especially the abdominal type (74), are more suggestive of a hyperactive HPA axis. Secretory rates of cortisol are elevated in most, but not all, studies, even when corrected for body surface area. Plasma cortisol concentrations, however, remain normal or slightly lowered (74,75), which is thought to be a result of increased plasma cortisol clearance. Indeed, many, but not all, human studies report increased urinary cortisol excretion rates in obesity (71). In addition, the urinary excretion of 5 $\alpha$ -reductase cortisol metabolites is positively

correlated with waist circumference in nonobese men and postmenopausal women, suggesting that fat accumulation in the upper body is associated with increased cortisol turnover (76). Thus, some, but not all investigators believe cortisol production is increased in upper-body obesity. Other indications of a hyperactive HPA axis include increased adrenal sensitivity to ACTH, increased responsiveness of ACTH and cortisol to CRH, and increased postprandial HPA activation (71). However, all these parameters have also been reported to be normal by other investigators, and most studies show comparable ACTH levels in obese and lean individuals (71). The concept that obesity is a CRH-deficient state, although substantiated by rat and molecular experiments, has further been contradicted by the finding of normal to only slightly lowered cerebrospinal CRH levels in obese humans (71).

In summary, it remains difficult to unequivocally relate obesity to consistent changes in the HPA axis. It seems likely that this axis is characterized by adaptations to the state of energy excess, analogously to the other hormonal axis involved in nutrient partitioning. However, the study of the role of the HPA axis in visceral obesity is complicated by several obstacles, which might partly account for the inconsistent findings. Early investigations studied different obesity phenotypes as one entity. This may have confounded the results considerably as regards cortisol, because central obesity with its cushingoid fat distribution might be associated with different dynamics of the HPA axis than lower-body obesity.

Another important factor is the influence of the many heterogeneous and often uncontrollable variables on the HPA axis. These complicate standardization for research purposes and subsequently interpretation of the results. The most significant confounder might well be the intertwined relationship among food intake, energy balance, and the HPA axis. Changes in body weight trigger counterregulatory mechanisms aiming to maintain the steady state, which are thought to be mediated by the HPA axis. Thus, compensatory mechanisms blur the effect of weight change, which is reflected in the fact that both overfeeding and starvation experiments have been found to amplify cortisol production (74).

In summary, an intertwined and complex relationship exists among energy balance, food intake, and several components of the HPA axis. In visceral (and, to a much lesser extent, in gluteofemoral) obesity, increased cortisol secretion and clearance rates result in normal or decreased plasma concentrations. There is no evidence of an increased exposure of cells and tissues to cortisol in visceral obesity, despite its similarities with Cushing's

syndrome. Whether changes on intracellular or receptor level are involved is unknown.

## Obesity and Mortality Rates

### I INTRODUCTION

“A certain amount of overweight has been looked upon with favor, our tendency being to consider a certain degree of hyper-nutrition to be desirable.”

—O. H. Rogers (1901)

“A sudden palpitation excited in the heart of a fat man has often proved as fatal as a bullet through the thorax.”

—W. Wadd (1829)

Since at least the mid-19th century there has been considerable interest and debate with regard to whether and how obesity is associated with mortality. Although a common view a century ago was that weights we would consider excessive today were innocuous and perhaps even desirable, case reports coupled with data from the life insurance industry suggested that excess weight and the central distribution of this weight were associated with shortened life expectancy (1).

Over the past several decades, the question of the effect of variations in body weight on mortality has become increasingly important. This is in part because both relative body weight and rates of obesity have been dramatically and steadily increasing in the United

States and most of the Western world (2–4). As agricultural and industrial technologies spread into the non-Western world, both the relative body weights and rates of obesity are increasing in those populations as well (5). Given this, it is not surprising that body weight is of considerable interest to the scientific community. Indeed, the “problem” of obesity has become the subject of governmental policies, public education campaigns, and insurance policies, and has become a major target of the food and pharmaceutical industries.

Despite efforts to address the rising rates of obesity, the effect of variations in body weight on mortality remains a controversial topic (6–9). Some studies (10–12) suggest that the relationship between measures of relative body weight (e.g., body mass index [BMI]: kg/m<sup>2</sup>) and longevity is decreasing, indicating essentially that one can never be too thin. On the other hand, some studies suggest that BMI has little important impact on longevity (13–15). Between these two extremes are studies that suggest that the relationship between BMI and mortality is U-shaped or J-shaped, indicating higher mortalities at the extremes of the BMI distribution (16–19). To complicate matters further, studies suggest that the BMI/mortality relationship may vary considerably as a function of demographic characteristics such as age, sex, and race (20–22).

In this chapter, we review briefly the literature pertaining to the association between BMI and mortality in humans. We also examine what is known about the effects of potential confounders of this association, most notably smoking, preexisting disease, and physical inactivity. We also review briefly studies that have investigated the potential moderating effect of variables such as age and race, as well as the effect of weight loss on mortality. Finally, we summarize the literature and provide recommendations for future research.

## II OVERVIEW OF THE EPIDEMIOLOGIC DATA

### A Methodologic Issues

There are a number of important methodologic issues pertaining to investigations of the association between obesity and mortality. At the core of these issues are certain assumptions, largely untested, pertaining to how best to analyze data from prospective cohort studies to estimate the effect of BMI on mortality (7,8,23,24). A detailed explication of these methodologic issues is beyond the scope of this chapter (see 25). However, we will consider four of the major methodologic issues because they speak directly to the validity of the conclusions that can be drawn from the literature: the effect of smoking, the effect of preexisting disease and weight fluctuation, the effect of physical inactivity, and the use of BMI as a proxy for measures of adiposity.

### B Effect of Smoking

Because smoking strongly increases mortality rate and also tends to be inversely associated with BMI (7), it is thought to contribute, artifactually, to the elevated mortality rate typically observed at the low end of the BMI continuum. If this were so, then failure to control for the effects of smoking might account for the overall J- or U-shaped BMI/mortality association commonly observed. If it is established that smoking consistently confounds this association, studies that have not controlled for the effects of smoking would have systematically underestimated the deleterious effect of high BMIs and overestimated the deleterious effect of low BMIs on mortality. Table 1 summarizes recent studies (12,17,26–36) that investigated whether smoking confounds the BMI/mortality association. As can be seen, with few exceptions (12,36), the vast majority of studies have found that the increased mortality among thin subjects (i.e., the J- or U-shaped association) persisted,

though was often attenuated slightly, after smoking was controlled for.

The minimal influence of smoking on the excess mortality among thin individuals is also supported by two comprehensive analyses. Troiano et al. (18) performed a quantitative synthesis of 19 prospective cohort studies and found a U-shaped relation between BMI and mortality regardless of whether smoking was controlled for statistically or if smokers were eliminated from the analysis. The BMI in the Diverse Populations Collaborative Group (37) analyzed pooled data from 15 separate epidemiologic studies involving over 200,000 subjects and found that the BMI/mortality association remained essentially unchanged (i.e., U-shaped) irrespective of whether or how smoking was treated in the analyses. Collectively, these quantitative syntheses suggest that smoking does not appear to be a major cause of the elevated mortality observed among the thin.

### C Effect of Preexisting Disease and Weight Fluctuation

In prospective studies of the BMI/mortality association it has become standard to analyze data excluding those cohort members who have died early (e.g., within the first 5 years of follow-up) as a means of controlling for confounding from preexisting diseases. The rationale for this is that many serious illnesses lead to both weight loss and an increased risk of death; thus, preexisting occult disease could confound the BMI/mortality relation and lead spuriously to the observed increase in the rate of mortality among persons with low BMIs. Thus, many reports (7,21,38) have advocated eliminating these “confounding deaths” by disregarding those persons who die early in the follow-up and analyzing only those deaths that seem less likely to have resulted from preexisting morbidities. This analytic approach seemed to become standard practice despite the absence of evidence pertaining to its effectiveness in reducing confounding due to preexisting disease.

To evaluate the effectiveness of excluding early deaths, Allison et al. (39) conducted three separate studies using analytic methods, Monte Carlo simulations, and meta-analysis. They showed that the use of “k-years exclusion” (i.e., excluding subjects who die during the first k years of follow-up) does not necessarily lead to a reduction in bias in the estimated effect of a risk factor on mortality when this relation is confounded by the presence of occult disease. Indeed, they demonstrated that such exclusion could actually increase the bias in some situations. Allison and colleagues (40) then conducted computer simulations using the

**Table 1** Effect of Smoking on BMI/Mortality Association

| Authors                          | Sample  | Follow-up (years) | Deaths | Covariates  | Results   |
|----------------------------------|---|-------------------|--------|---|---|
| Fontaine et al., 1998 (17)       | 1355 American women $\geq 50$ from the Panel Study of Income Dynamics                   | 4.5               | 110    | Age, BMI, smoking, education, 4 health status variables                           | U-shaped relation with and without smoking in the model   |
| Sempos et al., 1998 (26)         | 5209 Men and women from the Framingham Heart Study (28–62 yrs at baseline)              | 30                | > 1900 | Age, illness, education, smoking  | J-shaped relation; similar BMI at minimum risk of death for smokers and nonsmokers                                      |
| Brenner et al., 1997 (27)        | Cohort of 7812 male German construction workers (25–64 yrs at baseline)                 | Mean 4.5          | 167    | Age, nationality, alcohol, occupation, smoking                                    | Excess mortality in lowest BMI category reduced but not eliminated by control of smoking                                |
| Dorn et al., 1997 (28)           | 1308 Men and women from the Buffalo Health Study (20–96 yrs at baseline)                | 29                | 576    | Age, education, smoking   | U-shaped quadratic relation   |
| Chyou et al., 1997 (29)          | 8006 Japanese-American men living in Hawaii (45–68 yrs at baseline)                     | 22                | 2667   | Age, alcohol consumption, smoking   | J-shaped relation   |
| Seidell et al., 1996 (30)        | 48,287 Men & women (30–54 yrs at baseline)  | Mean 12           | 818    | Age, cholesterol, hypertension, diabetes, smoking                                 | In men, excess mortality in lowest BMI category reduced but not eliminated by control of smoking; no relation for women |
| Manson et al., 1995 (12)         | 115,195 Women (30–55 yrs at baseline) from the Nurses' Health Study                     | 16                | 4726   | Age, contraception, hormone use, family history of MI, menopausal status, smoking | Apparent excess risk associated with leanness eliminated when smoking was accounted for                                 |
| Wienpahl et al., 1990 (31)       | 5184 Black men and women (40–79 yrs at baseline) from the Kaiser Foundation Health Plan | 15                | 676    | Age, antecedent illness, education, alcohol use, smoking                          | J-shaped curve for men after controlling for smoking; flat association for women  |
| Landi et al., 2000 (32)          | 18,316 Patients admitted to 79 Italian clinical centers                                 | 2–3               | 548    | Comorbidities, smoking, alcohol use, cognitive impairment                         | U-shaped BMI/mortality association  |
| Visscher et al., 2000 (19)       | 7985 European men (40–59 yrs at baseline)   | 15–30             | 3807   | Age, study center   | U-shaped association; underweight among all smoking categories was a predictor of mortality                             |
| Yuan et al., 1998 (33)           | 18,244 Chinese men (45–64 yrs at baseline)  | 9                 | 1198   | Age, education, alcohol consumption   | U-shaped association between BMI and total mortality among lifelong nonsmokers  |
| Rissanen et al., 1989 (34)       | 22,995 (age > 25 years) Finnish men   | Median 12         |        | Age, smoking, cholesterol, blood pressure   | U-shaped high mortality in lean men “not entirely attributable to smoking”  |
| Wannamethee and Shaper 1989 (35) | 7735 (40–59 yrs at baseline) British men  | Mean 9            | 660    | Age, preexisting disease, smoking   | Increased mortality in lean men seen only in current smokers  |
| Garrison et al., 1983 (36)       | 5209 (28–62 yrs at baseline) respondents from the Framingham Heart Study                | 26                | 679    | Age, smoking  | BMI/mortality relation in lean subjects confounded by smoking   |

Source: Ref. 25.

actual BMI distribution and overall death rates from large databases representative of the U.S. population. These results were consistent with the analytical study in that removal of persons dying early in the study did not necessarily reduce bias in the estimated BMI/mortality curve due to confounding. While this simulation does not speak to whether or not the true relationship between BMI and mortality is U-shaped, it does indicate that exclusion of subjects who die early is not very effective at reducing bias, assuming such bias exists.

Finally, to investigate the effect of early death exclusion in actual data, Allison et al. (41) conducted a meta-analysis on 29 studies with almost 2 million subjects. This quantitative synthesis indicated that the difference in results when early deaths were included versus excluded was statistically significant but extremely small, and the shape of the curve did not change appreciably upon excluding early deaths. This suggests that the effects of exclusion of early deaths from the analysis are very small and not clinically significant (42).

These three lines of evidence suggest that excluding early deaths from analyses of BMI and mortality is not statistically sound. Thus, either the higher rates of mortality at lower BMIs are not simply artifacts from persons suffering from occult diseases, or such confounding does exist but eliminating early deaths is not effective in reducing this bias. To evaluate adequately the potential confounding effect of occult disease, we will need to develop more precise data collection methods to control for its influence. This will be a formidable challenge, however, since occult disease is, by definition, difficult, if not impossible, to identify.

Recently, excluding subjects who have lost more than some minimal amount of weight and/or have had more than some minimal degree of weight fluctuation has also become a popular analytic approach to address the BMI/mortality question (12,21,38,43). Like excluding early deaths, however, this practice has been used despite the absence of mathematical proofs, computer simulations, or detailed statistical discussions of its merits. Thus, before the practice of eliminating subjects with weight loss or weight fluctuation is promoted further, advocates of this technique should publish rigorous analyses and discussions of its merits.

#### **D Effect of Physical Inactivity**

It has also been suggested that the higher mortalities observed at high BMI levels could occur because many obese persons are sedentary and/or have poor cardiorespiratory fitness (44). In other words, because physical

activity is an important correlate of both body weight and general health, it is possible that physical inactivity and its byproduct, low fitness, not BMI, drives the association between obesity and mortality. It is also thought that physical inactivity/low fitness may help explain the J- or U-shaped BMI/mortality curve because a sedentary lifestyle, even among the thin, may be responsible for the increased mortality often observed in the low-BMI range (45).

Support for this so-called fitness-versus-fatness hypothesis comes primarily from prospective observational data from the Aerobics Center Longitudinal Study (ACLS). In a recent representative study from these data, Wei and colleagues (46) quantified the influence of cardiorespiratory fitness on cardiovascular disease (CVD) and all-cause mortality among 25,714 men classified as normal-weight, overweight, and obese men, and compared low fitness with other established mortality predictors (e.g., hypertension, current smoking). They found that low cardiorespiratory fitness was an independent predictor of mortality in all BMI-defined groups, even after adjustment for other mortality predictors. Roughly 50% of the obese men in the sample had low fitness, which produced a population-attributable risk of 39% for CVD mortality and 44% for all-cause mortality, suggesting that low fitness is a strong and independent predictor of mortality.

Consistent with this, Blair et al. (47) report that weight loss does not appear to be as important in reducing mortality rates as does an increase in cardiorespiratory fitness. Specifically, they found that, compared with unfit men who remained unfit, unfit men who improved their fitness level experienced a 44% reduction in all-cause mortality rate, independent of changes in weight during an average follow-up time of 5 years.

Data from the ACLS cohort also indicate that the apparent effect of fitness on reducing all-cause mortality rate increases linearly with increasing BMI, suggesting that the heaviest men may benefit most from improving their fitness (44). Similar results have been obtained in the Harvard Alumni Study in that a 23% reduction in all-cause mortality rate, independent of changes in BMI, was observed in men who began to engage in moderate to vigorous sports activity (48). Collectively, these studies suggest that low fitness adds to overweight and obesity in influencing mortality adversely.

Several methodological limitations, however, may limit the conclusions that can be drawn from these studies. First, most studies were conducted with middle-aged men of mild to moderate obesity who were in the middle- to upper-socioeconomic strata. Thus, it is

unclear whether these findings will generalize to, for example, severely obese persons, women, the elderly, and minority groups. Second, many studies investigating the relation among obesity and health and mortality have used relatively crude measures of self-reported physical activity as proxies for fitness. Thus, the effects of low fitness on the obesity/mortality association cannot be convincingly demonstrated with the current epidemiologic data. Third, it is important to distinguish between physical activity and physical fitness; that is, increasing physical activity may not confer the health benefits that appear to come with a quantifiable increase in aerobic fitness. Indeed, a recent meta-analysis (49) of 23 cohorts indicates that fitness and physical activity have significantly different relationships to combined CVD and coronary heart disease (CHD). Specifically, reductions in relative risk were nearly twice as great for fitness than for physical activity, suggesting that it is important to distinguish between physical fitness and physical activity, at least with regard to heart disease. Finally, because fitness, physical activity, BMI, and body composition are likely to be highly correlated, it is difficult to tease out the independent effect of these variables on mortality and morbidity.

In a recent randomized controlled clinical trial to evaluate the effects of weight loss and aerobic exercise on risk factors for coronary artery disease (CAD), Katznel et al. (50) randomized 170 healthy obese men to either (1) a 9-month weight loss (WL) intervention, (2) a 9-month aerobic exercise (AER) intervention, or (3) a weight maintenance control group. The WL group lost an average of 9.5 kg but did not change on  $VO_{2max}$ , whereas the AER group remained weight stable, but increased their  $VO_{2max}$  by 17%. The WL group has significant improvements in a variety of risk factors for CAD. Specifically, WL reduced fasting glucose concentrations by 2%, insulin by 18%, and glucose and insulin areas during oral glucose tolerance test (OGTT) by 8% and 26%, respectively. In contrast, AER did not improve fasting glucose or insulin concentrations or glucose responses during OGTT but did decrease insulin areas by 17%. Moreover, WL but not AER increased high-density lipoprotein cholesterol levels (13%) and decreased blood pressure compared with the control group. These findings indicate that weight loss improves CAD risk factors to a greater extent than does aerobic exercise training in healthy middle-aged and older obese men.

A recent published abstract (51), also from the Cooper Aerobics Fitness Center, describes the results of an analysis to investigate the association of BMI to

mortality after adjusting for cardiorespiratory fitness. Using data from over 11,000 men (aged 20–89 at baseline) with at least 10 years of follow-up (10–24 years), it was found that, after adjusting for age and cardiorespiratory fitness, obesity ( $BMI \geq 30 \text{ kg/m}^2$ ) was associated with a 1.95-fold increase in CVD mortality and a 1.46-fold increase in all-cause mortality. The association between obesity with both CVD and all-cause mortality remained strong (1.75 and 1.36, respectively) even when adjusting for, in addition to age and cardiorespiratory fitness, conventional risk factors such as smoking status, high blood pressure, diabetes, and parental CVD. This suggests, again, that obesity appears to have a potent effect on mortality, independent of cardiorespiratory fitness.

This is consistent with an analysis of data from the Buffalo Health Study (28) indicating that increased physical activity reduced the risk of all-cause (relative risk [RR] = 0.59) and coronary heart disease (CHD) (RR = 0.39) mortality among nonobese men, but not among obese men. Among women, increased physical activity reduced the risk of CHD death (RR = 0.26), but only among women aged < 60. By the same token, in an analysis of data from 631 sedentary adults from the HERITAGE Family Study (52) both body fat percentage and aerobic fitness were equally good predictors of future CHD (estimated using the revised Framingham Heart Study algorithm). However, in statistical models containing both body fat percentage and fitness (i.e.,  $VO_{2max}$ ), the removal of fitness from the model did not materially alter the fit of the model. In contrast, the removal of body fat percentage from the model containing only fitness changed significantly.

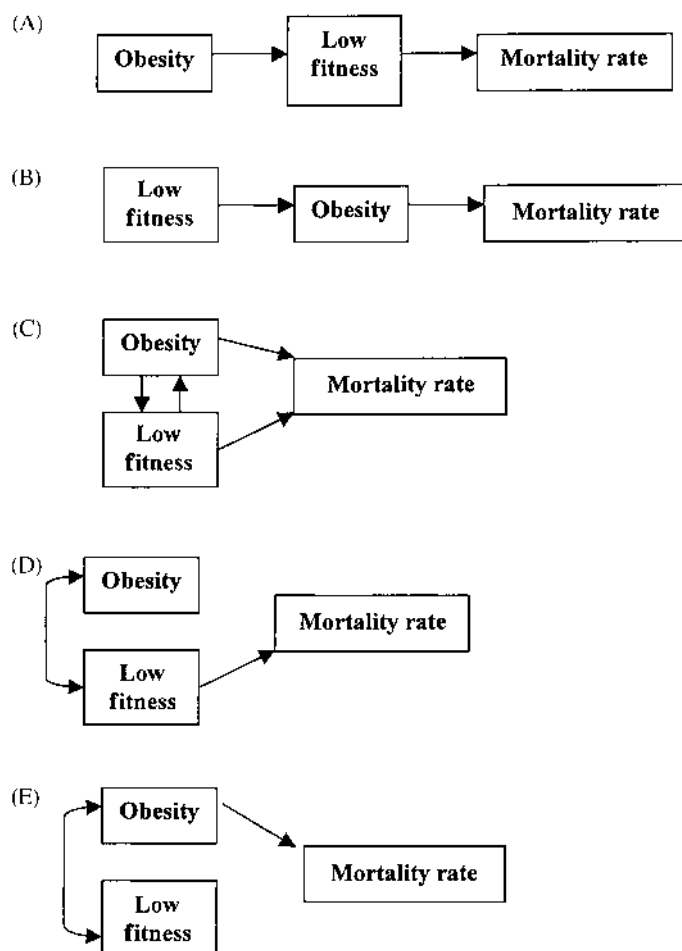

In sum, although some analyses of epidemiologic data demonstrate that physical inactivity and/or low cardiorespiratory fitness in overweight and obese adults are important predictors of mortality, recent randomized controlled clinical trials that have attempted to tease out the independent effects of weight loss and improved aerobic fitness suggest that weight loss may be more critical than fitness, at least with regard to improving CVD risk factors. However, a recent small-scale trial (53) suggests that, among men, exercise-induced weight loss reduces fat (particularly abdominal fat) and improves fitness significantly more than does diet-induced weight loss (see also 54). Moreover, reductions in insulin resistance, abdominal obesity, and visceral fat were similar in carefully matched subjects in the weight loss induced by diet and exercise groups. This implies that exercise alone (i.e., without dietary restriction) can be an effective strategy for reducing obesity and related

comorbidities. Obviously, before definitive conclusions can be made, additional randomized clinical trials should be conducted to assess the independent and interactive effects of physical activity, fitness, and body composition on health, function, and mortality.

In any event, conceptually speaking, as with obesity-related comorbidities such as hypertension and diabetes, it is unclear whether these are best considered potential confounders of the obesity/mortality association, as mediators along the causal pathway from obesity to mortality, or as independent influence.

Using path model notation as described by Bentler (55), we present five hypothetical causal models between

obesity (O), low fitness (LF), and mortality rate (MR) (see Fig. 1). In model A, O is hypothesized to cause LF, and LF increases MR. In this hypothetical situation, it is true that LF should be a stronger predictor of MR than is obesity and, after controlling for low fitness, obesity should have no independent effect on MR. However, in this case, LF is a mediating variable, not a confounder. Therefore, controlling for LF is inappropriate if one wants to ask what the total effect of O on MR is (7). In this situation, stating that O is not associated with MR after controlling for LF is akin to saying that having one's throat slit is not a risk factor for dying if one controls for blood loss. It is a true statement, but not very

**Figure 1** (A) Obesity causes low fitness and low fitness increases mortality rate. (B) Low fitness causes obesity and obesity increases mortality rate. (C) Obesity and low fitness reciprocally cause each other and collectively they increase mortality rate. (D) Obesity and low fitness are correlated but only low fitness increases mortality rate. (E) Obesity and low fitness are correlated but only obesity increases mortality rate.

informative, because it is hard to have one's throat slit and not lose blood.

In model B, LF causes O, and O increases MR. This hypothetical situation is the reverse of model A. In this instance, O should be a stronger predictor of MR than is LF and, after controlling for O, LF should have no independent effect on MR. Here, O is the mediating variable (not the confounder), and controlling for LF will not reduce the expected value of the apparent effect of O on MR. However, in finite samples, LF and O may be highly covariate and, therefore, controlling for LF may increase the variance of the estimated effect of O and cause it to be nonsignificant and/or lower even though it may have a real effect.

In model C, O and LF are strongly associated in that O is a cause of LF and LF is a cause of O and both increase MR. Controlling for O should attenuate the estimated effect of LF on MR, while controlling for LF should attenuate the estimated effect of O on MR. Due to the high correlation between O and LF, it will be difficult to "tease out" the independent effect of either O or LF on MR in such situations, and any model that includes one but not the other must be considered "misspecified" in the traditional statistical sense (56).

In model D, O and LF are correlated, perhaps due to some unspecified third factor. However, LF is the only factor that produces variation in MR. Model E is the reverse of model D in that O and LF are correlated with each other, but only O causes variation in MR. Models D and E are classic models of confounding and, under such circumstances, any model that includes one but not the other must again be considered misspecified and will lead to biased estimates of causal effects.

As models A to E illustrate, whether and how we control for O or LF when estimating the effects of either on MR depends, in part, on what we are prepared to believe about their causal relations. Moreover, each of the (nonexhaustive) possible sets of causal relations has very different biological and public health importance.

## **E Body Mass Index as a Proxy for Adiposity Measures**

Since BMI is highly correlated ( $\sim 0.70$ – $0.80$ ) to the percent of body weight as fat (57) and is easy to collect, it has been often used as the sole measure of relative adiposity in epidemiologic studies. However, the major difficulty in using BMI as a proxy for adiposity is that BMI is composed of two components, fat mass (FM), and fat-free mass (FFM). Thus, the use of BMI as a proxy for adiposity may mask any differential health consequences associated with both FM and FFM.

The majority of studies have shown that the rate of mortality associated with BMI is generally higher for both lower and higher BMI values and lower for moderate levels of BMI. As noted, the most common explanations for these J- or U-shaped curves are that persons with low BMI may smoke and/or suffer from preexisting diseases that increase their risk for mortality, independent of BMI. Another important hypothesis to consider, however, is that BMI, as a reflection of both adiposity and leanness, is not capable of capturing adequately the true relationship between body composition and mortality. Several studies have reported a positive health outcome for increased FFM and negative for increased FM (58). Thus, persons with low BMI may suffer from early mortality not because of BMI per se, but because inadequate levels of FFM increase their mortality rate. In other words, it may be that the risk of death increases with increasing FM and decreases with increasing FFM.

Allison and colleagues (59) investigated possible relationships between body composition and mortality using body composition measurements obtained on 1136 healthy subjects. Hypothetical mortality models were generated (using the real body composition data) in which mortality rate increased monotonically with FM and decreased monotonically with FFM. Using this model they showed that a U-shaped association between BMI and mortality could occur even when (1) mortality rate increased monotonically with FM, (2) mortality rate decreased monotonically with FFM, and (3) percent body fat increased monotonically, nearly linearly, with BMI. Thus, BMI may not capture adequately the effect of adiposity on mortality rate despite its high correlation with adiposity. This suggests that there is a need to conduct longitudinal studies that use precise body composition techniques to study the relationship between mortality rate and FM and FFM. Table 2 summarizes the few studies (60–68) that have evaluated the effects of FM and FFM (or imperfect proxies thereof) on mortality rate.

Folsom et al. (61) followed 41,837 women from the Iowa Women's Health Study Cohort for 5 years, testing the independent effects of BMI and waist-to-hip circumference ratio (WHR) on mortality rate. They found a U-shaped association between BMI and mortality rate. In contrast, WHR was strongly and positively associated with mortality in a dose-dependent manner. These findings were not altered substantially when controlling for potentially important covariates such as smoking, marital status, estrogen use, and alcohol use.

Keys et al. (60) examined 20-year coronary heart disease (CHD) incidence among 279 middle-aged Min-

**Table 2** Studies Evaluating the Effects of Fat Mass (FM) and Fat-Free Mass (FFM) on Mortality Rate

| Authors                         | Sample  | Measures of FM and FFM | Effect on Mortality Rate   |
|---------------------------------|---|------------------------|--|
| Keys, 1989 (60)                 | 284 Middle-aged men from the Twin Cities Prospective Study            | Hydrodensitometry      | FM had greater effect on mortality rate than did BMI   |

| Baik et al., 2000 (64)          | 39,756 Men from the Health Professional Follow-up Study               | Anthropometry          | Waist circumference positively associated with CVD mortality among men $\geq 65$ years             |
| Heitmann et al., 2000 (65)      | 787 Men from Göteborg, Sweden, born in 1913                           | Anthropometry          | FM monotonically increasing mortality rate; FFM monotonically decreasing mortality rate            |
| Lahmann et al., 2000 (66)       | 28,098 Adults from the Malmo Diet and Cancer Prospective Cohort Study | Bioimpedance           | % FM increased mortality rate in men but not women; FFM unrelated to mortality rate                |
| Allison et al. (submitted) (67) | 25,318 Adults from NHANES I and NHANES II follow-ups                  | Anthropometry          | Among men: FM monotonically increasing mortality rate; FFM monotonically decreasing mortality rate |
| Zhu et al. (submitted) (68)     |   |                        | Among women: FM U-shaped association; FFM monotonically decreasing mortality rate                  |

nesota men. Measures were taken of subjects' BMI, skinfolds, and body density by underwater weighing at baseline. Twenty-year incidence rates were then evaluated as a function of these variables. Results tended to be slightly stronger for measures of adiposity than for weight.

In a 10-year prospective study Menotti et al. (62) examined the association of BMI and skinfold measurements with mortality rate among 9550 adults. The results showed a consistent and clear U-shaped association between BMI and mortality. The analysis of skinfold data among men, however, was equivocal. Analyses of skinfold data among women, on the other hand, suggested a positive trend toward increasing mortality with increasing levels of adiposity. Notably, among women, the greatest risk was observed among those with low BMI and high skinfolds, a pattern suggestive of low FFM.

In sum, although the data are sparse (see Table 2), and the measures of adiposity are not as precise as we would like, the possibility exists that the elevated risks associated with excessively high BMIs are driven by adiposity rather than relative body weight per se.

### III POTENTIAL MODERATORS

#### A Age

Among older adults, studies indicate weak effects of obesity on mortality rate and/or very high nadirs (i.e., BMIs associated with lowest mortality) for the BMI/mortality curves (16,17,22,28,69,70). Using data from the Build Study on 4.2 million insurance policies issued between 1950 and 1971, Andres and colleagues found that the relation between BMI and mortality was U-shaped, and that the BMI associated with minimal

mortality increased consistently with age (71). In a Norwegian study (72), plots of the log of the mortality rate against BMI categories also revealed a U-shaped association. Although it was less clear whether the BMI associated with minimal mortality increased with age, the overall curves did flatten with age.

In a Finnish cohort of 17,000 women followed for 12 years, there was a U-shaped BMI-all-cause mortality relation among nonsmokers 25–64 years of age. Among women aged 65 or greater, mortality varied little according to BMI (73). Among white women from the Seventh Day Adventist cohort who never smoked, the RR of death associated with elevated BMI was lower among 55-to-74-year-olds than for 30-to-54-year-olds. For these older women, the minimal mortality was in the group with BMIs from 23 to 24.8 (74). Although the nadirs of the curves were much deeper, a recent study by Seccareccia et al. (75) of over 60,000 Italian subjects again showed the increase in the nadir with age.

Stevens et al. (21) investigated mortality over 12 years as a function of BMI across six age groups (30–44 years, 45–54, 55–64, 65–74, 75–84, and  $\geq 85$ ) among 324,135 never-smokers with no apparent preexisting disease from the American Cancer Society's Cancer Prevention Study I. Results indicated that, although greater BMI was associated with higher all-cause and CVD mortality, the RR associated with greater BMI declined somewhat with age (e.g., for men the RR of CVD mortality with an increment of 1.0 BMI unit was 1.10 for 30-to-44-year-olds and 1.03 for 65-to-74-year-olds).

Bender and colleagues (76) examined the effect of age on excess mortality associated with obesity among 6193 obese persons enrolled in the Dusseldorf Obesity Mortality Study (DOMS). When divided into four groups based on approximate quartiles of age and BMI, it was found that the overall risk of death increased with increased body weight, but that obesity-related excess mortality declined with age at all levels of BMI.

On the whole, these studies suggest that the relative increase in rate of death associated with increased BMI is somewhat lower for older adults than for younger adults, and that the BMI associated with minimum mortality rate increases with age. It is important to note, however, that BMI may not be a valid indicator of total fatness or fat patterning in older adults (i.e.,  $> 65$  years old). This is because older adults tend to have less muscle mass versus fat mass and more abdominal fat than younger adults at a given BMI (22). Finally, as Stevens et al. (77) point out, the absolute increase in rate of death can be higher in an older than in a younger person even when the relative increase is less.

## B Race

The majority of research on the effects of BMI on mortality has been conducted on samples of European-Americans (78). While it is clear that obesity in African-Americans, most notably women, is associated with a number of risk factors (79,80), the relation between obesity and mortality among African-Americans is not as clear as it is in Caucasian individuals.

In a cohort of 2731 African-American women members of the Kaiser Foundation Health Plan who were followed for 15 years, Wienpahl et al. (31) found an essentially flat BMI/mortality association across the entire range of BMI. However, although the U-shaped relation between BMI and all-cause mortality was not significant, Stevens et al. (81) found that, among African-American men, obesity was associated with increased risk of mortality from ischemic heart disease (IHD). More recently, Stevens et al. (82) examined the association of BMI to all-cause and CVD mortality among 100,000 Caucasian and 8142 African-American women from the American Cancer Society Prevention Study I. At the 12-year follow-up, a significant interaction was observed between ethnicity and BMI for both all-cause and CVD mortality. Specifically, among white women, BMI was associated with all-cause mortality in all four groups (defined by smoking status and educational attainment). In African-American women with less than a high school education, there was no significant association between BMI and all-cause mortality. However, there was a significant association among high school-educated African-American women. Models using the lowest BMI as the reference group among never-smoking women with at least a high school education indicated a 40% higher risk of all-cause mortality at a BMI of 35.9 in the African-American women versus 27.3 in the white women. Stevens et al. (82) concluded that, although educational attainment appears to modify the impact of BMI on mortality, BMI was a less potent risk factor in the African-American women than in the Caucasian women.

Two more recent relatively large and high-quality studies have emerged with samples of African-Americans (83,84). These studies show that there clearly is a deleterious effect of obesity on mortality rate among African-Americans, though the BMIs associated with minimum mortality rate may be slightly higher among African-Americans (85). Other investigators (43,86–89) have obtained similar results, suggesting that the effect of a given BMI increase on mortality rate may be less

deleterious among African-Americans than among Caucasians.

With regard to the BMI/mortality association among persons of other ethnic origins, data are sparse. In a sample of Micronesian Nauruans and Melanesian and Indian Fijians, obesity was not significantly associated with an elevated mortality rate (90). Among a sample of 8006 Japanese-American men living in Hawaii who were followed for 22 years, a significant quadratic (J-shaped) relation was found between BMI and mortality independent of the effects of smoking and alcohol consumption (29). Similarly, among a cohort of over 2000 Japanese adults over age 40, there was a U-shaped relation between BMI and mortality rate, with a nadir in the range of 23–25. However, in a cohort comprising 2,546 East Indian and Melanesian Fijians followed for 11 years, the association of BMI to all-cause and CVD mortality was generally inconsistent (91). Despite the known associations between body weight and diabetes and other obesity-related diseases found among Mexican-Americans, data have revealed lower-than-expected rates of mortality, based on known body weights (92).

Data on the BMI/mortality association among other ethnic groups (e.g., Native Americans, Alaska Natives) are limited. Hanson et al. (93) found that, among a cohort of 814 diabetic and 1814 nondiabetic Pima Indians, a U-shaped relationship between BMI and mortality was found in men but not in women. It was reported that excess mortality among lighter individuals was present in those persons who were losing weight. Thus, they concluded that preexisting illness might only partially explain the high mortality among lighter persons.

### C Family History/Individualization of Optimal BMI Target

Thus far, we have primarily considered “demographic” variables as potential moderators of the BMI/mortality association. However, one important set of variables that, to our knowledge, has yet to be investigated in this regard, involves family history and genetic information. We can envision family history/genetic information entering into models for the effect of obesity on mortality rate in several ways. In turn, this may allow the use of family history/genetic information in helping individuals determine the body weights likely to be associated with minimal mortality for themselves on a case-by-case basis.

First, it is well documented that susceptibility to many, if not most, diseases is, in part, genetically de-

termined (94). This includes several diseases for which obesity increases the risk, including heart disease (95), and at least one disease for which obesity decreases the risk, osteoporosis (96). Therefore, to the extent that individuals had a strong family history of heart disease and other diseases that are both heritable and made more likely by obesity and simultaneously had family histories of a lack of osteoporosis, lower-than-average body weights might be associated with minimal mortality for these individuals. Conversely, individuals with a strong family history of osteoporosis (or any other diseases protected against by obesity) and no family history of heart disease or other diseases made more likely by obesity, higher-than-usual BMIs might be most likely to confer the minimal rate of mortality for such individuals. Obviously, this conjecture warrants rigorous empirical evaluation before it can be accepted. Therefore, research involving related individuals in large longitudinal studies would be extremely useful. If this hypothesis is borne out, it might then be possible to use family disease history to help individuals optimize their own decisions about desired BMI levels.

Second, not only are obesity and certain obesity-related diseases partially heritable, it is possible that the propensities to suffer from ill effects of obesity are themselves partially heritable. For example, almost everyone knows some very obese person who died very early, plausibly as the result of his or her obesity. At the same time, almost everyone knows some very obese individual who lived a very long and healthy life. What factors influence these differential susceptibilities to the ill effects of obesity? To the extent that these factors are genetic, estimates of an individual's genetic susceptibility to the ill effects of obesity would be an important moderator of the BMI/mortality association. Moreover, family history might offer a potential way of providing such estimates; that is, if extensive family history about both BMIs and life spans could be obtained for individuals, one might be able to examine how much obesity did or did not confer added risk or protection within an individual family. Such information could be combined with baseline populationwide estimates of the increased or decreased risk conferred by obesity to come up with individual specific estimates. Certain random effects statistical models and empirical Bayes methods might be especially well suited to such analytic approaches.

Finally, as molecular genetic information continues to accumulate, we may eventually be able to identify specific genetic polymorphisms that are associated with the tendency for obesity to have a deleterious effect on

**Table 3** Recent Weight Loss and Mortality Studies

| Source                           | Sample  | Deaths        | Follow-up (years) | Results   |
|----------------------------------|---|---------------|-------------------|---|
| Williamson et al. (1995) (100)   | 43,457 White overweight nonsmoking women                        | 4199          | 12                | In those with obesity-related comorbidities intentional weight loss was associated with 20% reduction in mortality rate. No association between intentional weight loss and mortality rate in women without obesity-related comorbidities. Recent intentional weight loss of > 20 lbs associated with increased mortality rate. |
| French et al. (1999) (102)       | 33,017 Women from Iowa Women's Health Study                     | 1048          | 3                 | Intentional weight loss of $\geq 20$ lbs not associated with higher CVD mortality risk. Unintentional weight loss of $\geq 20$ lbs associated with 26–57% higher total mortality risk and 51–114% higher CVD mortality risk.  |
| Williamson et al. (1999) (103)   | 49,337 White men aged 40–64                                     | 9360          | 12–13             | Among those with no reported health problems, intentional weight loss not associated with total, CVD, or cancer mortality rate. Among men with health problems, intentional weight loss was not associated with total or CVD mortality but with increased cancer mortality risk.  |
| Pamuk et al. (1993) (104)        | 5192 Adults from NHANES I Epidemiologic Follow-Up Study         | 533           | 12–16             | Weight loss of > 5% maximum lifetime body weight associated with increased death rates even after excluding deaths within first 5–8 years after baseline.   |
| Wee et al. (2000) (105)          | 18,494 Respondents of the 1989 National Health Interview Survey | 1282          | 5.5 mean          | Intentional weight loss of 5–10 lbs associated with lower hazard of death compared to reference group. Greater than 10-lb weight loss did not significantly increase longevity.   |
| Lee and Paffenbarger, 1992 (106) | 11,703 Men in the Harvard Alumni Study                          | 1441          | 12                | Both weight loss and weight gain of > 5 kg significantly increased all-cause and CHD mortality.   |
| Blair et al., 1993 (107)         | 10,529 Men from the Multiple Risk Factor Intervention Trial     | 380           | 6–7               | Weight loss associated with increased risk of death (range of relative risk = 1.04–3.42). Lowest mortality in weight stable.  |
| Williamson et al., 2000 (101)    | 4970 Overweight adults with diabetes                            | 1325          | 12                | After adjusting for initial BMI, sociodemographic factors, health status, and physical activity, intentional weight loss was associated with 25% reduction in total mortality and 28% reduction in CVD and diabetes mortality.  |
| Higgins et al., 1993 (108)       | 2500 Adults from the Framingham Heart Study                     | Not specified | 20                | Among men, weight loss associated with higher 20-year all-cause, cardiovascular, and CHD mortality compared with weight-stable group.   |
| Diehr et al., 1998 (70)          | 4317 Nonsmoking adults from the Cardiovascular Health Study     | 539           | 5                 | Among overweight (BMIs 26.2–27.3) older adults (aged 65–100) a > 10-lb weight loss in the year preceding the study had 5-yr mortality rates that were similar to those who were weight stable in the year prior to the study.   |

longevity. If such polymorphisms could be detected and had large individual effects, then it might be possible to use such genetic information in gene by environment (or, more aptly, gene by phenotype) interaction analyses. Again, such polymorphisms could be examined for individuals to help them determine the best BMI for themselves.

Clearly, the ideas put forward in this section are concepts for which we do not currently have supporting data. Nevertheless, they are all quite consistent with existing knowledge, and we think it only a matter of time before such more complex and individualized statements about optimal BMIs with respect to longevity can be made.

## D Weight Loss and Mortality

Dramatic effects of obesity on mortality rate have been demonstrated in studies of laboratory rodents (97). Specifically, when obese animals are compared to nonobese animals, the nonobese outlive the obese. These findings are consistent with the life-prolonging effects achieved by caloric restriction (CR). CR should not be confused with lower body weight or lower body fat. However, CR clearly results in lower body weight and is the most common method by which humans achieve lower body weight. Therefore, it is worth noting that CR achieved by various means and resulting in weight loss has been demonstrated to result in increased longevity in a variety of animal species (98).

Obesity, at least when severe, is clearly associated with an increased mortality rate, and weight loss is associated strongly with reductions in many risk factors (99). Therefore, it seems reasonable to conjecture that weight loss among the obese will increase life span. Indeed, some studies suggest that intentional weight loss reduces mortality rate in persons with obesity-related comorbidities such as hypertension (100) and diabetes (101). Among apparently healthy overweight and obese adults, however, the majority of studies (71,102–108) suggest that intentional weight loss is associated with an increase in mortality rate (see Table 3) (20,109). Find-

**Figure 2** Estimated hazards ratios (to the last category) of individuals in the corresponding categories of weight changes in kg (WC) and fat change (FC; change in skinfolds thickness in mm), and their standard errors (SE) from the Tecumseh Community Health Study. The numbers in parentheses represent the minimum and maximum values for the corresponding quintile-defined categories. For both WC and FC, the positive and negative values represent gains and losses, respectively. (From Ref. 60.)

**Figure 3** Estimated hazards ratios (to the last category) of individuals in the corresponding categories of weight changes in kg (WC) and fat change (FC; change in skinfolds thickness in mm), and their standard errors (SE) from the Framingham Heart Study. The numbers in parentheses represent the minimum and maximum values for the corresponding quintile-defined categories. For both WC and FC, the positive and negative values represent gains and losses, respectively. (From Ref. 60.)

ings such as these prompted Andres et al. (20) to conclude that no matter what population is studied, or how the data are “cleaned,” treated, and analyzed, “Evidence suggests that the highest mortality rates occur in adults who either have lost weight or have gained excessive weight. The lowest mortality rates are generally associated with modest weight gain” (p 737).

This puzzling finding is the subject of considerable inquiry (110). Among the important research challenges associated with investigating the effects of weight change on mortality with current epidemiologic data are: (1) the appropriateness of basing estimates of the benefits or risks of weight loss on self-reported intentionality; (2) the potential confounding effects of smoking and preexisting disease; (3) the difficulty of assessing and accurately taking account of weight regain after weight loss; (4) assessing dietary changes during follow-up; and (5) the use of body mass index (BMI: kg/m<sup>2</sup>) as a proxy for both fat mass and fat-free mass.

Another important issue to consider is the unknown efficacy and safety of many weight loss practices. Methods for intentionally inducing weight loss include fad diets, herbal supplements of untested safety (111), bulimia, and other potentially unsafe dietary practices. Hence, it appears ill advised to estimate the effects of weight loss achieved by medically recommended methods by studying weight loss that is merely reported to be

“intentional.” What is needed are studies of weight loss produced among obese humans by modern methods that are accepted by mainstream medicine.

As discussed previously, studies that have used BMI as a proxy for adiposity may not provide the best estimate of the impact of obesity or weight change on mortality. In this regard, Allison et al. (60) investigated change in weight and fat (via skinfolds), across two time points, and mortality in two epidemiologic studies—the Tecumseh Community Health Study and the Framingham Heart Study. In both studies, weight loss was associated with an increased mortality rate, while fat loss was associated with a reduced mortality rate. Specifically, each standard deviation of weight loss ( $\sim 5.5$  kg across both studies) was estimated to increase the hazard of mortality by  $\sim 35\%$ . In contrast, each standard deviation of fat loss (10.0 mm in Tecumseh and 4.8 mm in Framingham) reduced the hazard of mortality by  $\sim 16\%$  (see Figs. 2,3). Thus, among individuals that are not severely obese, weight loss is associated with increased mortality rate, and fat loss with decreased mortality rate. If confirmed, these results suggest that weight loss should be recommended only under conditions where a sufficient proportion of the weight lost would be fat. Unfortunately, the conditions required to produce such a weight loss remain unknown, as is the exact proportion that is “sufficient.”

## IV SUMMARY AND RECOMMENDATIONS

### A Overall Findings

The aforementioned methodological issues, most notably the use of BMI as a proxy for adiposity measures, suggest strongly that the current epidemiologic data may not provide us with the best estimates of the obesity/mortality association. Nonetheless, describing what the available data show is relatively simple. When the overall body of literature is reviewed, the data clearly show that the association between BMI and mortality is U- or J-shaped. Among nonelderly white males and females, the nadirs of the curve tend to be around the mid to high 20s for BMI. Though isolated studies may occasionally show other results, these conclusions are clearly supported by the overall body of data (18).

The relationship between BMI and mortality, however, appears to vary substantially by age and race, and it is likely that other variables, not yet identified or fully explored, may also moderate this relationship. It seems ill advised, therefore, to generalize from studies in one population (e.g., white middle-aged females) to other

populations (e.g., elderly Asian females). Thus, one should refrain from making broad statements about the overall “average” relationship between BMI and mortality for the U.S. population unless such a statement is based on data that are representative of the U.S. population.

### B Effect of Potential Confounders

While smoking is a plausible confounder of the BMI/mortality relationship, in practice, adjusting for smoking or excluding smokers from the analysis has very little effect on the results. This does not imply that one should not control for smoking, only that smoking does not appear to account for the U- and J-shaped relationships frequently observed in BMI/mortality studies. Nonetheless, some have argued (38) that smoking may still account for the high mortality at the lower BMI range since statistical adjustment for smoking may not address the nuances involved in smoking such as depth of inhalation and genetic susceptibility. Of course this does not explain why the J- and U-shaped association is still typically observed when “ever-smokers” are omitted from the analysis.

Excluding early deaths is not a reliable way of controlling for confounding due to occult disease. In the presence of such confounding, exclusions can either increase or decrease the bias, although in practice such exclusions appear to make little difference (39). However, because exclusions can actually increase the bias under some circumstances and result in a reduction of sample size, we do not recommend that subjects dying during the first few years be excluded from analyses. The same can be said for the practice advocated recently of excluding individuals with recent weight loss or weight fluctuation (until and unless evidence is brought to bear that shows otherwise).

A number of studies have demonstrated that low cardiorespiratory fitness increases mortality rate, suggesting that the BMI/mortality association may be confounded by fitness. It is important to note, however, that the majority of these observational studies were conducted in middle-aged white men. It is unclear, therefore, whether these results generalize to women, the elderly, and minority groups. Moreover, most studies that have investigated the relationship between obesity and health/mortality have tended to rely on self-reports of physical activity rather than fitness per se. Thus, although a physically active lifestyle may promote fitness and thus attenuate the increased rate of morbidity and mortality observed among obese persons, more

sophisticated research designs and assessment techniques are required to tease out the independent effects of obesity and fitness on mortality. Indeed, recent randomized controlled clinical trials suggest that weight loss appears to have a greater effect on CVD risk factors than does improving cardiorespiratory fitness, implying that obesity may play a more central role in morbidity and mortality than fitness. Nonetheless, further research is required to disentangle the independent effects of obesity, a sedentary lifestyle, and poor fitness on health, morbidity, and mortality.

### C Effects of Weight Loss

Intentional weight loss among persons with obesity-related comorbidities such as diabetes appears to reduce mortality rate. However, among apparently healthy overweight/obese adults, intentional weight loss seems to neither decrease nor increase mortality rate. Given that these findings were derived from observational studies that relied on self-reported intentionality of the weight loss, they should be interpreted with caution (110). Nonetheless, the current data suggest that remaining weight stable or increasing body weight slightly associates with lower mortality.

### D BMI Versus Body Composition Measures

Though highly correlated with adiposity, BMI is not a true measure of adiposity and we cannot therefore assume that BMI will have the same relationship with mortality as will a more precise measure of body composition. Indeed, studies that have used other body composition measures suggest that distinguishing fat mass from fat-free mass may be required to determine the “true” effect of obesity on mortality, as well as the effect of intentional weight loss on mortality.

Given the quality of the data and the methodological issues outlined throughout this chapter, many of the conclusions drawn from the literature are, at best, tentative. Consistent with most clinical and basic laboratory research, however, it is clear that high levels of BMI (i.e., BMIs > 30) are associated with increased mortality rate. In contrast, over the range of BMI from about 28 on down, the picture is not clear. The data suggest that lower BMIs are associated with increased mortality. However, this is inconsistent with the clinical evidence suggesting that intentional weight loss generally associates with a reduction in morbidities (99). Moreover, these data run counter to the results of

animal research indicating that caloric restriction is capable of producing substantial increases in longevity (98).

### E Explaining the J- or U-Shaped Association

The reasons that persons with lower levels of BMI are at greater mortality risk than those with midrange BMIs are not known. However, as we have shown, smoking is probably not a sufficient explanation for this phenomenon. A possibility that has not been considered seriously is that being in the mid-BMI range may actually cause one to be at lower risk of death from certain causes. For example, relative to thinness, it is clear that being in the mid-BMI range is protective against osteoporosis (112,113). Moreover, there is a clear biological mechanism because thinness is a significant risk factor for hip fracture (114), and these fractures, in turn, increase mortality rate (112,115).

It is also possible that lifestyle factors may explain some of the excess mortality associated with thinness. It has been demonstrated in data from the 1990 Behavioral Risk Factor Surveillance Survey that thin men and women were more likely to be sedentary and to consume high-fat diets than normal-weight adults (116). Moreover, data from the ACLS indicates that thin men and women with low aerobic fitness had the highest mortality rates (117). Thus, for at least some persons with low BMI, unhealthy lifestyles may contribute to a higher mortality rate and may help account for the J- or U-shaped BMI/mortality association.

Though more speculative, it is also possible that, relative to being in the mid-BMI range, people in the low BMI range are more potently affected by or more susceptible to certain forms of infection, injury, or disease (e.g., cancers). Finally, given that most Americans, as well as people of many other countries, do not consume adequate amounts of fruits, vegetables, fiber, and many micronutrients (e.g., 118), it may be that thin people, simply by virtue of eating less total food, are at increased risk of nutrient deficiencies despite sufficient caloric intake to remain weight stable. That is, just as laboratory animals live longer under conditions of CR, provided they have adequate micronutrient intake (119, 120), thinness in humans may be deleterious only because, for some people, it may be associated with inadequate intake of certain nutrients.

Since it is possible that thinness causes increased mortality rate, we believe potential explanations, like those we have proposed, should be investigated, and that further research is required to understand rather

than simply to “explain away” the counterintuitive observation of elevated mortality rate among the thin.

## V CONCLUSIONS AND FUTURE DIRECTIONS

Even if viable biological mechanisms to explain the apparent elevated mortality in the lower range of BMI were established, it is clear that the current literature has been derived from suboptimal epidemiologic data; that is, BMI, the measured independent variable, is only a proxy for adiposity, the “true” independent variable. Moreover, occult disease, the most plausible confounding factor, is not measured but inferred.

In our view, investigators have tried to compensate for the suboptimal data by using sophisticated statistical approaches. We believe, however, that no statistical technique, no matter how elegant, can produce valid conclusions from data that are unable to address directly the obesity/mortality association. We contend that valid conclusions pertaining to the obesity/mortality association are most likely to come if we use better measurements and study designs. In our view, the optimal study would be a long-term large scale randomized controlled clinical trial (121) that included: (1) a sample of persons along a broad range of BMI (mildly overweight to severely obese); (2) serial measures of body composition; (3) thorough and ongoing clinical evaluations of health status; and (4) in addition to mortality as an endpoint, the use of clinically relevant markers of subclinical disease as outcomes.

In the interim, we must rely on thoughtful and careful epidemiologic investigations using the available observational data. However, as the design and measurement techniques used in observational studies become more sophisticated and more widely used, we will be in a better position to draw valid conclusions regarding the obesity/mortality association.

## Etiology of the Metabolic Syndrome

**Per Björntorp**

University of Göteborg, Göteborg, Sweden

### I INTRODUCTION

One significant and rapidly developing area of obesity research is the etiology of the metabolic syndrome and its prevention and treatment. The syndrome exhibits the central, visceral subtype of obesity, which is an integral part of the syndrome and bears the most serious somatic hazards of obesity, while the peripheral, subcutaneous subtype is associated mainly with mechanical problems arising from the increased body weight.

Historically, the clustering of the symptoms now called the metabolic syndrome has been observed and documented since the beginning of the 20th century. There is little consensus on the definition, although many different proposals have been advanced, particularly after addition of new components to the core of the syndrome. Most authors agree on the inclusion of insulin resistance, abdominal obesity, dyslipidemia, and hypertension, since these established risk factors for cardiovascular disease, type 2 diabetes mellitus and stroke are the reason the metabolic syndrome is of major importance.

Techniques for evaluation of the major components of the syndrome have changed little since the previous edition of the Handbook of Obesity (1998) (1), probably because the methodology continues to be adequate. However, questions exist about certain simple anthropometric measurements; for example, the waist/hip circumference ratio (WHR). It is a poor measurement of intra-abdominal, visceral fat mass, a major statistical

determinant of most of the comorbidities, yet its statistical power is surprising. Possibly this measurement contains unrecognized information beyond intra-abdominal fat mass, such as a muscle component included in the hip circumference measurement. These issues are an area for more research.

At the time of the first edition, research on endocrine perturbations focused on the disturbances of regulation of the hypothalamic-pituitary-adrenal (HPA) axis and its interference with the central gonadal and growth hormone axes. Major advances have occurred with the development of new techniques, which are sensitive and discriminating enough to reveal minor regulatory errors of daily life (2–4). Research has previously addressed the peripheral consequences of the endocrine perturbations (accumulation of intra-abdominal fat and insulin resistance) (5,6), perturbations in the capillary system and in the synthesis of myosins (1). Much progress has been made in these areas and in genetics since the previous edition. The original Handbook examined the period up to 1996–1997, so this chapter will focus on the following years, including generally integrated and specific aspects of these developments covered in several recent reviews (2–9).

### II DEFINITION OF THE METABOLIC SYNDROME

A syndrome is a collection of symptoms typically occurring together. Such syndromes often originate from

errors not in a single organ or tissue, such as in myocardial infarction, liver cirrhosis, or brain tumors, but from overriding systemic control of the function of several organs. Multiple consequences can result, causing difficulty in diagnosis. Such syndromes often begin as basic symptomatic description, but if the basic etiology becomes clearer, treatment shifts from symptomatic to causal.

The metabolic syndrome is usually considered to include two major symptoms, insulin resistance and visceral obesity, with the addition of hypertension and dyslipidemia in the form of elevated circulating concentrations of triglycerides and triglyceride-rich very low density lipoprotein (VLDL) particles and low concentrations of high-density lipoprotein (HDL) particles. The major question is whether these apparently divergent symptoms can be collected under one common etiological mechanism.

The metabolic syndrome may arise from a component of the syndrome, acting alone or in combination with other factors. The list includes insulin resistance, visceral fat, endocrine dysregulation (cortisol, androgens, insulin, growth hormone), obesity, and/or genetics. Let us first consider the possibility that a single symptom causes the other components of the metabolic syndrome.

#### **A Insulin Resistance as a Primary Pathogenic Factor**

Reaven (10) examines whether insulin resistance could be the primary factor, resulting in dyslipidemia and hypertension. The relationship between insulin and dyslipidemia seems to be well established; however, a recent review (9) casts doubt on the concept that hypertension results from hyperinsulinemia alone. Reaven's cluster of common risk factors is the first synopsis of variables for what he terms "Syndrome X" and is supported by evidence, much from Reaven's own excellent research. Syndrome X may, however, be considered to be part of a larger syndrome, commonly called the metabolic syndrome, which also contains visceral obesity as a major component. While reasonable due to the well-documented close connection between visceral obesity and insulin resistance (11), it is difficult to imagine how insulin resistance with compensatory hyperinsulinemia might increase visceral fat mass. Therefore, other etiological primary events for the metabolic syndrome must be considered.

#### **B Visceral Fat as a Primary Pathogenic Factor**

Could the other major component of the metabolic syndrome, visceral fat accumulation, be the primary

factor? One hypothesis is that free fatty acids (FFA), from the enlarged, lipolytically very active visceral fat stores delivered to the hepatic portal vein, would generate risk factors by hepatic mechanisms (12). This is an attractive hypothesis for generation of dyslipidemia in the metabolic syndrome because both insulin and delivery of FFA limit the rate of synthesis of lipoproteins in the liver. Peripheral systemic hyperinsulinemia might result from diminished hepatic clearance of portal insulin, and cause peripheral insulin resistance by a secondary downregulation of insulin receptor density. Possibly large enough concentrations of portal FFA can leak out into systemic circulation (even with 50% liver reabsorption) to cause muscular insulin resistance (13).

There are a few concerns with this hypothesis, however. First, these are theoretical considerations, lacking direct information because of the difficulty of examining the flow of FFA and insulin in the portal vein in humans. But there is indirect support (12,13) as well as recent data suggesting that hepatic exposure to FFA might well be elevated, provided FFA release from not only the portal but also the systemic circulation is included (14). Another problem is that the hypertension of the metabolic syndrome does not fit well unless hyperinsulinemia is the primary factor, which is not always the case, as discussed below. Furthermore, and most importantly, this hypothesis does not explain the apparently selective accumulation of depot fat in the visceral, "portal" adipose tissues. This is not a simple consequence of obesity in general where fat is normally harmoniously deposited in several depots, including subcutaneous regions. In summary, although this hypothesis has some merit and may apply to some symptoms of the metabolic syndrome, it does not seem to fully explain the etiology.

The remaining core symptoms of the metabolic syndrome, hypertension and dyslipidemia, are difficult to visualize as primary etiological factors for visceral obesity and insulin resistance. In principle, factors other than the cluster of symptoms in the metabolic syndrome could be involved as primary pathogenic factors.

#### **C Hormones as a Primary Pathogenic Factor**

Hormones are the major regulators of metabolic events. Could the metabolic syndrome be a consequence of endocrine dysregulation? The similarities between Cushing's syndrome and the metabolic syndrome are quite apparent, not only for distribution of fat depots but also for insulin resistance, dyslipidemia, hypertension, and certain diseases associated with these symptoms. Could the metabolic syndrome be a hypercortisolemic condi-

tion? It is a difficult question. Cortisol's effects can be hidden because it is difficult in vivo to measure, yet in general they support the hypothesis, and numerous studies show a connection.

Measurements of cortisol secretion and its regulation via the hypothalamic-pituitary-adrenal (HPA) axis are complicated, even in conditions of clearly elevated secretion, such as Cushing's syndrome. HPA axis regulation is easily disturbed by external environmental factors (15). Therefore, noninvasive sampling in ordinary circumstances is probably required to reveal minor, putative abnormalities as seen in obesity and the metabolic syndrome.

Another factor causing difficulty is the complex regulatory machinery of the HPA axis, with stimulating, amplifying and feedback inhibitory stations that result in a specific, diurnal rhythm with discrete peaks of varying magnitude and duration. This drowns single measurements of cortisol. Evidence now indicates that the kinetics of the diurnal curve might provide information different from that of total cortisol secretion (2,3); i.e., although urinary excretion of free cortisol might be measurable if the organism has been exposed to elevated circulating cortisol, a low excretion of cortisol does not necessarily equal a normal regulation of the HPA axis. Furthermore, the status of the HPA axis regulation is probably best examined by stimulatory or inhibitory tests.

### III ASSOCIATION OF THE METABOLIC SYNDROME AND ELEVATED CORTISOL LEVELS

Recent studies (16,17) have shown a link between stress, salivary cortisol levels, and the metabolic syndrome, using relevant population samples (2,3) (See Fig. 1.) About two-thirds of a group of middle-aged Swedish men and women exhibited an apparently normal diurnal saliva cortisol curve, measured under ordinary life conditions and examined with low dose dexamethasone. However, ~25% of the men reported stress during the day of measurements (curve labeled "stress" in Fig. 1). In these men, the daytime saliva cortisol levels differed dramatically. Rather than a peak upon awakening followed by a sharp drop in the morning, the stress pattern peaked at lunch, and decreased drastically in the afternoon/evening hours. This resulted in an elevated total cortisol secretion over the day. Although varying effects of dexamethasone may have flawed some of these cases, indicating a need for stronger methodology (3), other studies have shown similar values (18). The immediate wake-up peak appears to be significant. Subjects

Figure 1 Saliva cortisol in men. (From Refs. 2,16.)

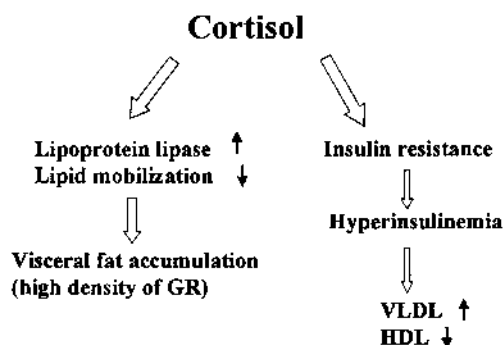

in a stressful milieu have lower saliva cortisol values upon awakening which then do not "unwind" normally (19). The delayed downwinding of morning cortisol is echoed in controlled animal experiments (20), where stress exposure precedes hypersensitivity of the HPA axis at peak activity (night in rodents, early morning in humans). The tentative conclusion from this information is that ~25% of the populations examined may have an HPA axis regulation linked to stress experiences that cause elevated cortisol levels. This conclusion is significant when coupled with another finding of the Swedish study (16,17).

In the men who reported stress during the day of measurements and who had elevated total cortisol, constituting ~25% of the total population (See curve labeled "stress" in Fig. 1), there were direct associations between cortisol measurements and several features of the metabolic syndrome (16,21). Cortisol measurements, particularly those relating to perceived stress and after food intake, correlated directly with measurements of visceral obesity, insulin resistance, dyslipidemia, and blood pressure. These findings suggest a quantitative connection between cortisol secretion and the metabolic syndrome. The associations are clearer after HPA axis challenges (stress and food intake) than with baseline cortisol values in steady state (16,21). Similar observations with elevated basal and/or stimulated cortisol secretion in central, visceral obesity (22–29) and other cardiovascular risk factors (30–35) have now been made by several other laboratories.

#### A Effects of Cortisol

Cortisol is well known to cause peripheral insulin resistance, and the mechanisms have been clarified (36).

**Figure 2** Cortisol, in the presence of insulin, induces visceral fat accumulation by expression of lipoprotein lipase and inhibition of lipid mobilization. Cortisol also induces insulin resistance, followed by compensatory hyperinsulinemia which is responsible for increased levels of triglyceride-rich VLDL and low levels of HDL.

Furthermore, cortisol is known to direct the storage of fat to visceral depots, as seen most typically in Cushing's syndrome, and the mechanisms have been defined at the cellular and molecular levels as reviewed previously (5). In brief, in the presence of insulin, cortisol stimulates pathways for lipid accumulation (lipoprotein lipase) while inhibiting lipid mobilization. This is mediated via the glucocorticoid receptor, with particularly high density in visceral fat. The dyslipidemia of the metabolic syndrome (high triglycerides; triglyceride-rich, low-density lipoproteins; and low high-density lipoproteins) can be derived from the insulin resistance and subsequent hyperinsulinemia via a combination of hepatic events, combined with a diminished removal of triglyceride-rich particles in the periphery (10). The remaining symptom, elevated blood pressure probably results from parallel activation of the HPA axis and sympathetic nervous system. High insulin levels might facilitate this stimulation. This is summarized in Figure 2.

In summary, cortisol elevation clearly seems to be able to induce the metabolic syndrome through known mechanisms. This is also seen in Cushing's syndrome and in patients treated with glucocorticoids, where abnormalities vanish when cortisol excess is removed (37). It may then be concluded that human subjects who show an increased cortisol secretion or who are treated with glucocorticoids will be likely to develop the metabolic syndrome as a consequence (see Fig. 2).

## B Nature of Dysregulation of the HPA Axis in the Metabolic Syndrome

Cortisol secretion is innately vulnerable to regulatory errors, or dysregulation of the HPA axis, which would

explain the elevated cortisol secretion in the metabolic syndrome. Factors causing regulatory errors of the HPA axis include sensitization (facilitation) of activating mechanisms, deficient feedback control, or a combination of the two. Genetic susceptibility at several levels can affect all these factors. Briefly, the pathway involves corticotropin-releasing hormone (CRH) and adrenocorticotropin hormone (ACTH), which mediate central facilitating mechanisms to regulate cortisol secretion, as does a feedback mechanism of glucocorticoid receptors found in several places, including the hippocampus (Fig. 3).

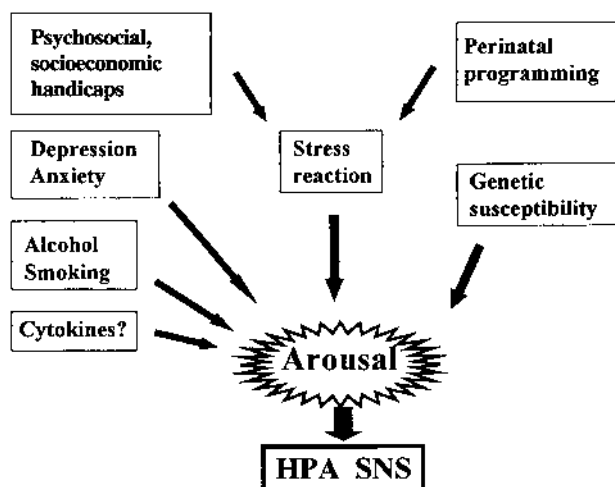

There are data supporting the hypothesis of an inefficient feedback control, although the results are not conclusive. However, the most probable point for significant regulatory errors appears to be facilitation of central regulatory mechanisms, resulting in hypersensitivity of the HPA axis and reflecting an association between long-term stress and abnormal HPA axis regulation (18–20).

That facilitation of the central regulatory mechanisms occurs is suggested by elevated cortisol secretion in the morning, during the most active phase of diurnal regulation, as seen in animal studies (20). Facilitation can result from frequent activation of the HPA axis and subsequent downregulation of the density of the central glucocorticoid receptors (38). The stress sensitivity during the examination period may arise from such facilitating factors, and has also been observed in other studies (26,27,39).

Further support is found in statistical associations with HPA axis activation. These include factors that tend to create a stressful surrounding socioeconomic and psychosocial handicaps with resulting frequent activation of the HPA axis, or depression and anxiety

**Figure 3** Regulation of the hypothalamic-pituitary-adrenal axis. Facilitating factors ("stress") induce the secretion of CRH, ACTH, and cortisol. Cortisol binds to glucocorticoid receptors in the central nervous system, which control the activity by a feedback mechanism.

**Figure 4** Arousal of the HPA and the central SNS is induced by perceived stress from psychosocial and socioeconomic handicaps. These reactions might be sensitized by perinatal programming. Depression, anxiety, alcohol use, smoking, and, possibly, cytokines cause direct activation. Genetic susceptibility predisposes for these reactions.

traits, alcohol, and smoking, which activate the HPA axis directly (39–43). Thus, in brief, environmental factors, psychological traits, and stimulants, as well as certain physiological elements, appear to negatively affect the regulation of the HPA axis, resulting in excess cortisol and consequent metabolic syndrome (Fig. 4).

#### IV CAUSES OF HPA AXIS DYSREGULATION IN THE METABOLIC SYNDROME

A number of factors that are known to stimulate the stress centers indirectly or directly in the metabolic syndrome in cause-effect relationships are shown in Figure 4. They can be classified as environmental stressors, stimulant usage, and physiological events.

##### A Environmental Stressors

Stress, both psychosocial and socioeconomic, can affect the HPA axis. Several cross-sectional studies show correlations between various psychosocial handicaps and components of the metabolic syndrome (2–4,39,40,43). Nonhuman primates, when subjected to controlled psychosocial stress, develop a submissive, depressive type of reaction. Adrenals become enlarged as a sign of increased secretory activity, and the suppressibility of cortisol secretion becomes diminished.

Furthermore, sex steroid hormone secretions are diminished, a known consequence of long-term HPA axis activation (45). This is followed by insulin resistance, impaired glucose tolerance, dyslipidemia, elevated blood pressure, early coronary atherosclerosis, and visceral fat accumulation (46,47). This mirrors the metabolic syndrome effects seen in our studies with humans subjected to psychosocial stress.

Cross-sectional evidence indicates association between socioeconomic stress and the metabolic syndrome (2,3,18,39). In the Whitehall studies, a socioeconomic gradient is inversely associated with central obesity and signs of the metabolic syndrome (48). In the men of our studies, a similar socioeconomic-education gradient shows the same associations and, in addition, signs of increased stress-related cortisol secretion and a poor dexamethasone suppression. Furthermore, these endocrine and somatic risk factor phenomena are proportional to time of exposure of socioeconomic handicaps (49). These observations might be considered as prospective intervention studies and suggest that long-term socioeconomic handicaps are followed by stress reactions along the HPA axis with subsequent generation of the metabolic syndrome, which amplifies the risk for coronary artery disease and diabetes. This might be the pathway via which social inequality leads to disease.

##### B Psychological Traits

Mental depression classically elevates activity of the HPA axis and the sympathetic nervous system, and anxiety with panic symptoms behaves similarly (50). Depression is followed by an increased risk of developing myocardial infarction and type 2 diabetes mellitus in randomized, prospective population studies (51,52). The risk at least equals that of elevated plasma lipids, hypertension, or insulin resistance. An increased visceral fat mass has recently been demonstrated in melancholic depression (53). The metabolic syndrome is associated with minor, subclinical depressive symptoms (1,2,7,41,42). Mental depression may increase the risk for serious somatic disease via the increased cortisol secretion creating the metabolic syndrome. Depressive symptoms in the population (41,42,54) may have the same consequences. This area has recently been reviewed (7).

##### C Stimulant Usage

Alcohol is known to activate the HPA axis above blood concentration of ~0.1%, which is reached after about two drinks. Alcohol overconsumption without nutritional deficiencies is followed by enlargement of visceral

fat depots (55). In severe cases of alcohol abuse, the so-called pseudo-Cushing syndrome may develop, which mimics the effects of the true Cushing's syndrome, and is improved or cured by alcohol abstinence (56). Alcohol consumption at moderately elevated levels has been found to be associated with signs of the metabolic syndrome (39). Alcohol may consequently be an additional factor in the generation of the metabolic syndrome through HPA activation.

Tobacco smoking is frequently found in metabolic syndrome patients (11) and is known to be followed by increased cortisol secretion (57). Smokers have an increased visceral fat mass, diminishing with smoking abstinence (58). Smoking also induces insulin resistance (59) and consequently the major factors of the metabolic syndrome.

In summary, psychosocial and socioeconomic handicaps, depression and anxiety, alcohol, and smoking are statistically associated with increased diurnal cortisol secretion. These factors have been shown in separate experiments to be followed by HPA axis activation, increased cortisol secretion, and the metabolic syndrome. Several of these studies have an intervention component, the results of which strengthen the argument for a cause-effect relationship. This suggests that the statistical association of these factors with the metabolic syndrome is caused by an elevated HPA axis activity and cortisol secretion (See Fig. 4).

It is not possible to state which of these factors is the most powerful in the individual case. It seems likely that they are mixed and interrelated. One may, for example, visualize a chain of events starting out with psychosocial or socioeconomic misfortunes, followed by abuse of stimulants and depressive symptoms. This chain might, however, start with any of the separate factors as the initial trigger.

## V PHYSIOLOGICAL ELEMENTS

Certain physiological events also correlate to the metabolic syndrome, including aging, cytokine exposure, and the small-baby syndrome.

### A Aging

Aging may be another stimulating factor. The changes in regulation of the HPA axis after repeated stress resemble those of aging. In aging rats, the unwinding of cortisol after a challenge is delayed, probably owing to a diminished efficacy of the controlling feedback (60). Aging humans show similar effects, but the effects

cannot be separated from those of the unavoidable stressful events of a long life (61,62).

### B Cytokines

Recently several studies have shown that elevations of C-reactive protein and cytokines are associated with the metabolic syndrome and risk for cardiovascular disease (63,64). Cytokines, particularly interleukin-6, are powerful stimulators of the HPA axis, probably explaining the elevated cortisol secretion during infections (65,66). It therefore seems possible that chronic infections activate the HPA axis via cytokines, inducing the same cascade of events as described above with generation of conventional risk factors (see Fig. 4). This problem is under study.

### C Small-Baby Syndrome

Children born small for gestational age have been shown, with strong statistical correlations in several studies, to develop the metabolic syndrome with increased risk for cardiovascular disease and type 2 diabetes mellitus at adult age (67). Results of recent studies suggest that such subjects also show signs of an increased cortisol secretion and a sensitive HPA axis (34,35). The question, then, is, why do children small for gestational age develop a sensitive HPA axis?

Recent experimental studies in rats now provide likely explanations. Prenatal immune challenges, such as exposure to lipopolysaccharides, cytokines, or glucocorticoids, result at adulthood in apparently permanent changes in the sensitivity of the HPA axis. One common denominator for several of these agents might be a stimulation of secretion of endogenous glucocorticoids which may interfere with the sensitive development of neuroendocrine regulations. The locus of impact seems to vary with time of exposure and power of the intervention agent, and is localized to the mechanisms facilitating central HPA axis stimulation or to the feedback control by downregulation of the density of central glucocorticoid receptors responsible for the feedback signals (68–70). The consequences effect body fat mass, insulin sensitivity, and sex steroid hormones. Fetal cytokine exposure during the first 8–12 days of pregnancy produces in adulthood a condition like the metabolic syndrome in terms of stress sensitivity, sex steroid abnormalities, elevated body fat accumulation, and insulin resistance (69).

Postnatal impacts are also important for adult outcomes. For example, one injection of testosterone to

newborn female rats results in metabolic syndrome-like symptoms at adulthood (71), while excess corticosterone exposure during this period results in lean adult rats (72).

These results demonstrate clearly that the perinatal period is very sensitive to various impacts which can result in permanent neuroendocrine, metabolic and body composition changes. Apparently numerous factors mediate such impacts, several of which are of potential interest for the human situation. Lipopolysaccharides and cytokines produced during maternal infections might inflict stress on the preborn baby. The original Barker (67) publications suggested that intra-uterine underfeeding might be involved, inducing over-secretion of glucocorticoids as active agents in an HPA axis programming.

The Dutch Famine studies provide additional clues. Mothers subjected to the famine during early pregnancy had children who developed obesity and risk for cardiovascular disease, while children of mothers exposed late in pregnancy were small and developed hypertension and diabetes (73). It seems likely that this apparent difference in adult outcome was due to the impact of central regulatory systems at different sensitive periods.

We have recently started to examine the birth records of the subjects in our populations. Preliminarily, it appears that the HPA axis abnormalities at adulthood are found in men born small for gestational age, which agrees with the recent reports by Phillips (34,35). One aim of these studies was to estimate how often the metabolic syndrome in adulthood can be traced to birth factors. Not all birth records have been located. However, data from subjects with missing birth records do not differ from those whose birth records have been found, suggesting that selection bias is not a problem. Estimations from the prevalence of children currently born small for gestational age (<5%) suggest that this pathway to the metabolic syndrome might not be of major importance today, whereas the prevalence of a sensitive HPA axis in middle-aged adults seems to be in the order of 25% (16). Fetal undernutrition might have been more important in the U.K. 70–80 years ago, when the subjects examined by Barker (67) were born. There may, however, be other active factors than fetal undernutrition with perinatal exposure leading to sensitization of the HPA axis, such as alcohol, tobacco smoking, and infections, which might be more important today. This is an area of major importance for observations and advice during pregnancy.

In summary, the small-baby syndrome appears to be a pathway leading to metabolic syndrome at adulthood. The mechanism might be a permanent sensitizing of the

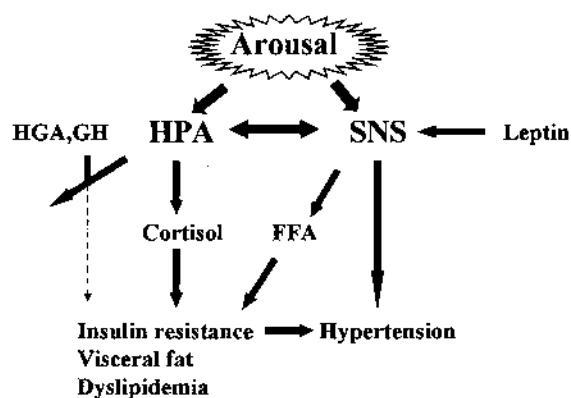

HPA axis to challenges during adult life. The pathogenic mechanism therefore probably resembles that described in the studies in adult populations (see Fig. 4). Accumulating evidence suggests that the mechanism involves interference with normal central regulations during sensitive periods of brain development. This might be compared with the long-term development of a “thrifty genotype,” but is in contrast a “thrifty phenotype,” developing from the impact of factors during pregnancy. The quantitative role of this pathway into the current adult prevalence of the metabolic syndrome cannot be estimated with any certainty, but the input by the condition of low birth weight appears from indirect estimations to be relatively small. This area of research has clearly demonstrated the power of perinatal factors to influence adult health.

## VI OTHER VARIATIONS OF HPA AXIS DYSREGULATION

### A Cortisol and Burnout

In addition to the stress pattern of cortisol secretion, another pattern is shown in Figure 1—the burnout curve, representing <10% of the men. In that group, there was a very low morning value and low cortisol all over the day. Dexamethasone suppression seemed to be blunted, with strong associations to anthropometric, metabolic, and hemodynamic risk factors. These men also showed low values of testosterone and IGF I (16), a surrogate measurement of growth hormone secretion. In this group, cortisol by itself is unlikely to be generating the risk factor, but it seems possible that low testosterone and growth hormone secretions might be responsible. Both these hormones, when low, are followed by insulin resistance and visceral fat accumulation (5,6). When testosterone or growth hormone is added, insulin sensitivity is regained and fat is mobilized. These mechanisms are essentially known (5,6). These are opposite effects to those of cortisol, and it seems likely that the outcome in terms of the components of the metabolic syndrome is in fact dependent on the balance between cortisol on the one hand and sex steroid and growth hormone on the other. In fact, the metabolic syndrome is also seen after isolated growth hormone or testosterone deficiency (74–76) (see Fig. 5). The markedly elevated blood pressure and heart rate suggest an increased activity of the sympathetic nervous system, a known consequence of a failing HPA axis, perhaps a compensatory mechanism (77). This might amplify insulin resistance by excess mobilization of free fatty

**Figure 5** Arousal of the HPA is followed by elevated cortisol secretion and inhibition of the HGA and GH axes, resulting in insulin resistance, visceral fat accumulation, and dyslipidemia (the metabolic syndrome). Concomitant activation of the central SNS is followed by elevated mobilization of FFA, amplifying insulin resistance, and induces hypertension, facilitated by insulin and leptin.

acids, which are elevated in the metabolic syndrome (78) (see Fig. 5).

The reason for the pronounced derangement of the HPA axis regulation in these rather few men is not fully understood. Over time and under continuous stress, the HPA axis first reacts normally but eventually does not unwind in a normal pace after the stress challenge stops. After further development, total cortisol secretion goes down, resulting in a rigid, flat diurnal curve. This has been considered to be the case when the HPA axis is “burned out” and might, over a sufficiently long time, become irreversible and end up with actual substance loss in areas of the brain where glucocorticoid density is high, such as the hippocampus (79). These changes have been seen in “vital exhaustion,” after severe “life events,” in war veterans, Holocaust victims, repeated melancholic depression, and Cushing’s syndrome, all conditions with prolonged elevated cortisol secretion (79). Elevated cortisol itself may have such damaging effects, which appear to be amplified by various toxins, including alcohol (38,60).

The men with a flat “burned-out” cortisol secretion also report psychosocial and socioeconomic handicaps, anxiodepressive traits, smoking, and alcohol consumption, which are slightly higher than those of the other subjects. Alcohol reporting is, however, notoriously unreliable and overuse might be a hidden factor. A time factor may also be involved, the men in question having been exposed to damaging factors longer than the others.

## B Follow-up Studies of the Male Subjects

The cortisol secretory pattern of the men has been subjected to further analyses. As seen in Figure 1, three subgroups can be separated as follows. The normal group has high morning values, and lower prelunch values. The stressed men have lower morning cortisols, which are unchanged before lunch. The “burned-out” men have still lower morning values, which remain low. This means that morning and prelunch cortisols contain most of the information of interest for evaluation of the basal cortisol secretion pattern. Using only these values and the testosterone values for categorization of the neuroendocrine status of these men, essentially similar associations to risk factors remain as in the more detailed statistical analyses utilizing all measurements (16,21).

The men in this population have now been followed up after 5 years. The simplified categorization outlined above shows in preliminary analyses that the development of any new event of hypertension, diabetes mellitus, angina pectoris, or myocardial infarction can be predicted by the cortisol-testosterone measurements of 5 years ago. Consequently there are proportionally fewer events in the normal group, more in the stressed group, and the highest incidence is in the “burned-out” group (Wallerius et al., to be published).

If these observations hold true in further calculations, they strongly support the interpretation of the chain of events suggested in this overview, summarized in Figures 4 and 5, which is, as far as we know, the first longitudinal observation of the relationship between neuroendocrine stress reactions and disease. The power of this new risk factor seems impressive, providing information on development of disease or disease symptoms during such a short period of time in a comparably small cohort. These simple measurements may prove to be useful in screening for risk for development of serious somatic disease in a stressful environment.

## VII WOMEN AND HYPERANDROGENICITY

The endocrine, anthropometric, and metabolic findings reported above are generally applicable to both men and women. The results in women, however, show several interesting differences (17). A major difference is the involvement of androgens in women. We were particularly interested in this phenomenon, having shown previously that a relative hyperandrogenicity (HA) is associated with a powerful risk of developing type 2 diabetes mellitus, cardiovascular disease, hypertension,

**Figure 6** The risk ratio for development of type 2 diabetes mellitus in women in relation to sex hormone binding (SHBG) quintiles. (From Ref. 80.)

and endometrial cancer, followed by premature mortality (11). In fact, the risk of developing diabetes increased 10- to 20-fold among the women with HA, irrespective of menopausal state (80) (see Fig. 6). Calculations of population attributable risk indicate that HA may explain no less than 50–67% of all development of type 2 diabetes in women. HA may thus be one of the most powerful risk factors for serious disease in women. The risk seems to affect the highest quartile of testosterone values in women (17) and may therefore be considered to be a common risk factor in the general population of women. This risk factor has attracted surprisingly little attention. Androgens showed consistent, strong statistical associations to anthropometric, metabolic, and hemodynamic risk factors in women. This was particularly pronounced for free, active testosterone (T) but was also seen for cortisol, androstenedione, and dihydroepiandrosterone sulfate (DHEAS), which are secreted mainly or exclusively from the adrenals.

Values for  $17\beta$ -estradiol were low. The associations to cortisol measurements were not as strong as in men, and certainly not as strong as to androgens in the women. Concentrations of the stronger androgens (T and free T) correlated closely not only with weaker androgens (androstenedione and  $17\text{-OH}$  progesterone) but also with hormones directly associated with the activity of the HPA axis (ACTH, DHEAS, and cortisol measurements) (17). It therefore seems likely that the more powerful androgens are also at least partly of adrenal origin.

As expected, measurements of abdominal obesity also showed strong associations to the metabolic risk factors and blood pressure. Androgens and abdominal obesity were mutually dependent. Partial correlations or stepwise regression analyses performed on their associations to risk factors showed that the two contributed independently (17). It is therefore apparent that androgens and abdominal obesity both contribute to the development of disease risk in women (Fig. 7).

T administration to women is followed by accumulation of visceral fat, where estrogens might have a protective effect (81,82). T administration to women or female rats is also followed by systemic insulin resistance, localized to the glucose transporter and glycogen synthase systems in muscle (83–85). It is thus clear that androgens in women are directly associated with the metabolic syndrome, and the effect is likely to be causal. However, the generation of risk factors is in part apparently due to factors other than androgens involved in central fat distribution and obesity, which then in turn amplifies the risk factor generation (17).

Again, as in the men, the question comes up as to whether there are factors that would be suspected or known to activate the HPA axis. Indeed, approximately the same factors as in men are associated with HA, including psychosocial and socioeconomic handicaps, depression and anxiety, smoking, and alcohol (17). We believe that these factors activate the HPA axis in the same way as in the men, resulting in hypersecretions from the adrenals, where, in women, androgens seem to be more powerful in their damaging effects than cortisol, while the opposite seems true in men. It seems highly likely, although not measured, that the men with evi-

**Figure 7** In women, central arousal is followed by central obesity and elevated androgens, probably at least partly of adrenal origin, which are mutually dependent and are followed by the metabolic syndrome. Aromatase might be malfunctioning, amplifying the effects of arousal of the hypothalamic-pituitary-adrenal axis. (From Ref. 17.)

dence of elevated activity of the HPA axis also secrete excess adrenal androgens, but this small increase in total androgen production in men is probably insignificant for peripheral effects, and is hidden in the much larger gonadal production. However, in the women, we cannot overlook HA generation from the ovaries.

The explanation of HA effects in the women is then likely to be at least partly due to activation of the HPA axis with androgens oversecreted from the adrenals. Androgens in circulation are converted to estrogens via the enzyme CYP-450 aromatase. Interestingly, women with HA have a polymorphism in the aromatase gene, localized to the microsatellite of the fifth intron. This microsatellite, consisting of the tetranucleotide repeat TTTA, is shorter than average in the HA women (17). The low estrogen/androgen ratio in these women is compatible with a deficient function of the aromatase, although direct measurements of enzyme activity have not yet been performed. Such a short microsatellite has previously been reported in women with an elevated risk to develop breast cancer or osteoporosis (86,87), and is therefore an association of major interest for development of serious disease in women.

It also turns out that nonsmoking women in this population, who at age 42 have managed to keep their body weight constant since the age of 21, have high estrogens and low androgens, resulting in a high estrogen/androgen ratio, compatible with an excellent function of the aromatase enzyme. Their microsatellite in the aromatase gene is longer than average, and there is no overlap between the number of tetranucleotides in the groups of abdominally obese, hyperandrogenic women, described above, and the lean women with low androgens (88) (Fig. 8). Thus, we have two groups of women who are different not only phylogenetically but are totally opposite in the obesity and risk factor pattern, in the sex steroid hormones, and in microsatellite repeat sequences in the aromatase gene.

Recently it has been shown that a knockout of the aromatase gene is followed by not only elevated androgens in female mice, but also by abdominal obesity (89). We therefore speculate that the aromatase function is a regulator not only of androgen levels in women, but also of the tendency to develop visceral obesity and the metabolic syndrome. Women with a deficient function based on an aberrant allele in the aromatase gene might be particularly susceptible to the metabolic syndrome with abdominal obesity when exposed to a stressful environment. There is a clear possibility that the short allele in the aromatase microsatellite indicates a poor function of the enzyme, followed by abdominal obesity and the metabolic syndrome.

**Figure 8** Distribution of tetranucleotide repeats in the microsatellite of the fifth intron of the CYP 450 aromatase gene in women in the population. Obese, hyperandrogenic women have a stretch of the tetranucleotide repeats corresponding to 168–171 bp's and lean, healthy women an average stretch of 187 bp's. (From Refs. 17,88.)

Abdominal obesity in women is closely associated with HA and increased risk to develop endometrial and mammary carcinomas (11). These are hormone-dependent cancers, and one might consider the hypothetical possibility that HA might be involved in the pathogenesis.

## VIII HYPERTENSION IN THE METABOLIC SYNDROME

The relationship among blood pressure, obesity, and insulin is much debated, with controversial results (Fig. 5, right part). Numerous studies show a relationship among blood pressure, insulin resistance, and hyperinsulinemia; several others find none; still others show a mixture of results in subgroups. This was summarized in an excellent comprehensive review by Rocchini in the previous edition of the Handbook (90). Correlation studies therefore do not give much promise for this direction of research. Rocchini suggests that insulin affects blood pressure regulating mechanisms selectively, which might explain the controversies in correlative findings.

Such mechanisms include enhanced sodium retention but the picture is unclear. There is considerable evidence that insulin causes sodium retention in acute experiments, but the presumed long-term conse-

quence—volume expansion with elevated blood pressure—does not seem to have been conclusively shown (90). Such a consequence seems rather unlikely, because volume-regulating mechanisms should prevent it (91). Furthermore, the concept of salt-induced pathogenesis of primary hypertension has in general been received with considerable doubt, at least within a normal range of salt intake variation, although a possibility exists of subgroups with genetically salt-sensitive individuals (91). Thus, the argument for an insulin-mediated retention of salt in obesity and hypertension is weak.

Another mechanistic hypothesis is that insulin may act via stimulation of the central sympathetic nervous system (92). This hypothesis is hard to prove in humans because of the difficulties in measuring activity of the sympathetic nervous system. For example, plasma concentrations or urinary outflow of catecholamines are measurements of the activity of the total sympathetic nervous system, but a concentration sufficient to regulate blood pressure might be too small to be detected.

Direct measurements of activity in sympathetic nerves in relation to insulin levels during hyperinsulinemic clamp procedures do not provide long-term information (93). Patients with insulinoma and chronically elevated insulin levels do not become hypertensive, and successful surgery is not followed by changes in blood pressure (94). A major difficulty with this entire approach to the problem is, however, that primary hypertension in humans develops through several stages; increased sympathetic nervous system activity is present only in the early stages and is absent later (91). Meaningful studies therefore need to define the stages of development of hypertension. Most studies seem to have been performed in established hypertension, where increased sympathetic nervous system activity would not have been expected to be present.

Primary hypertension develops through an initial phase of hyperkinetic circulation, due to frequent activation of the sympathetic nervous system (95). Long-term follow-up studies indicate that this transitions into a stage, which is dominated by a peripheral circulatory resistance developed through adaptive processes (96). The evidence for such a stage and the involvement of the central sympathetic nervous system in early phases are considerable, and this pathogenic pathway of hypertension seems to have reached a consensus in the field of hypertension research (97). These observations are based on subjects with or without obesity, with varying degrees of insulin resistance and hyperinsulinemia. There is evidence that insulin activates the central sympathetic nervous system (92). It may therefore be presumed that a development towards hypertension

would be more likely to occur or to be more pronounced, if insulin amplifies sympathetic nervous system activity in hyperinsulinemic conditions such as in the metabolic syndrome.

There is, however, convincing evidence for other primary events. Already Brod (98) in the 1950s could show an increased stress sensitivity in early stages of hypertension. Such observations are corroborated by striking epidemiological observations. Nuns in a secluded cloister in northern Italy have been followed through decades and do not see increased blood pressure with age, unlike women of similar ages living outside the calm environmental conditions of the cloister. The difference is apparent also after adjustments for obesity, diet, alcohol intake, and childbirth (99). The difference in blood pressure development seems to be best explained by the psychosocial environment.

Another similar example comes from the Kuna Indian tribe, where individuals who moved into a large, boisterous city developed hypertension, while those remaining in their ordinary habitat, or moving to a calm environment outside the same city, remained normotensive. Salt intake does not appear to have played a role because the salt intake is rather high in this tribe and similar irrespective of habitat (100). Again these observations support the detrimental influence of a stressful environment for the development of hypertension.

Direct prospective evidence is provided by studies in the United States, where increase in blood pressure with time, carefully measured continuously during ordinary life conditions, is proportional to environmental stress (101). Taken together, this evidence strongly suggests influence by environmental stress factors as an important pathogenic feature of primary hypertension. When the metabolic syndrome with insulin resistance and hyperinsulinemia is added, it seems likely that insulin might amplify blood pressure elevation with insulin as an active component (see Fig. 5).

These results allow a consideration of another important factor. As reviewed above, the metabolic syndrome seems to have a background of HPA axis activation, due to environmental factors, where perceived stress from psychosocial and socioeconomic problems are important ingredients. In animals, there is a profile of different stress reactions depending on the perception of a threatening challenge. With apparent possibilities to cope with the challenge, the sympathetic nervous system is activated with elevated blood pressure—the fight-flight reaction. When the threat seems overwhelming, a depressive, defeat reaction occurs with activation of the HPA axis and a secondary inhibition of growth

and gonadal axes. This activation may shift from one to the other depending on the situation of danger or pressure, and is often mixed (102). In humans, these profiles are less apparent. It is in fact difficult in humans to activate one of these centers without affecting the other. This is probably because the central regulation of the HPA axis and the sympathetic nervous system are tightly interconnected at several levels (45).

The primary pathogenic triggers for the metabolic syndrome seem to be central factors activating the HPA axis. The data from the hypertension research field indicate a similar origin for primary hypertension. The parallel origin opens up the possibility that primary hypertension and the metabolic syndrome might have a common central origin through parallel activation of both stress centers in the lower part of the brain, the HPA axis, and the sympathetic nervous system.

A remaining question, then, is which is the dominant factor in activation of the central sympathetic nervous system, environmental stress factors or insulin? When blood pressure is the dependent variable in partial correlation analyses correcting for several components of the metabolic syndrome, including abdominal obesity and insulin, only measurements of the HPA axis remain as a determinant of blood pressure (103). This illustrates the connection between the HPA axis and blood pressure in the men from the Swedish population sample, where the majority does not have an established hypertensive condition, which probably means that secondary regulatory factors of blood pressure such as in established hypertension are not involved. Furthermore, insulin has apparently less importance for the determination of blood pressure than HPA axis activity. More detailed studies of this problem in a smaller group of men show associations between measurements of the HPA axis against blood pressure response to laboratory stress, feeding, and corticotropin-releasing hormone administration and excretion of catecholamine metabolites (104), again indicating the close connection between the HPA axis and blood pressure regulation.

With this background it seems reasonable to suggest that the hypertension of the metabolic syndrome is actually due to a parallel activation of both stress axes, the HPA axis and the central sympathetic nervous system. The statistical associations between insulin and blood pressure, frequently reported in the literature, might therefore be due primarily to the HPA axis being responsible for the insulin elevation, with a parallel activation of the blood pressure regulating part of the central sympathetic nervous system (Fig. 5).

Another recent development of interest for the pathogenesis of hypertension in the metabolic syndrome is the connection between the leptin and the sympathetic nervous systems. Leptin is produced mainly in adipose tissue and is elevated in both obese animal models and obese humans, in proportion to adipose tissue mass (105). Although it was found early that leptin not only induces satiety via a hypothalamic receptor and stimulation of thermogenesis, recent studies have indicated that leptin also activates the part of the sympathetic nervous system that regulates blood pressure. Most obese animal models have both elevated leptin levels and elevated blood pressure. When leptin is infused systemically or intrathecally, blood pressure rises, and animals genetically engineered to overproduce excess leptin become hypertensive (106). Exceptions are the Zucker rat and the db/db mouse, which have a mutation in the leptin receptor (106). These observations indicate that leptin is responsible for the hypertension seen in obese animal models, and that this is mediated through the leptin receptor.

In human studies, polymorphisms in the leptin receptor gene locus are associated with lower blood pressure. These polymorphisms include Lys109Arg in exon 4, Gln223Arg in exon 8, and Lys656Asn in exon 14. This is particularly clear in obese subjects where the differences between subjects with normal and variant alleles are important not only statistically but clinically and are in the order of 15/10 mm Hg systolic/diastolic blood pressure. Furthermore, when hypertensive men ( $> 140/90$  mm Hg) were examined separately, they were overweight or obese and had elevated leptin levels. Only one out of 64 of these hypertensive men had normal alleles in the leptin receptor gene (107). Although not showing cause-effect relationships, these results suggest that the leptin system might also be of importance for blood pressure regulation in humans, and might show why not all obese people are hypertensive. The metabolic syndrome is often combined with obesity, so this mechanism might be of importance for blood pressure regulation in this syndrome, particularly since the central sympathetic nervous system clearly seems to be involved, as reviewed above (Fig. 5).

In summary, there are thus three major explanations of hypertension in the metabolic syndrome, namely, elevations in sympathetic nervous system activity, insulin, and leptin arising from accompanying obesity. The triggering factor in the early stages of primary hypertension is probably frequently elevated sympathetic nervous system activity. The high prevalence of hypertension in the metabolic syndrome with obesity is likely

to be caused by additional effects of elevated leptin and insulin, stimulating sympathetic nervous system centers (Fig. 5).

## IX ROLE OF OBESITY IN THE METABOLIC SYNDROME

Visceral fat accumulation is part of the metabolic syndrome. This is, however, not the same as obesity, which is defined as an increased body fat mass, irrespective of localization. The question, then, is whether or not obesity is part of or associated with the metabolic syndrome.

Obesity of the gluteofemoral or peripheral type may occur without the metabolic syndrome (108). Furthermore, elevated visceral fat accumulation may occur without increase of total body fat such, as with aging or smoking (11). These examples show that visceral fat and obesity are two different entities. Nevertheless, obesity and proportionally increased visceral fat accumulation frequently occur simultaneously (11). In fact, in the statistical calculations of the Swedish population samples (16,17), estimations of central waist circumference (WHR), visceral fat accumulation (abdominal sagittal diameter), and estimations of total body fat (BMI) are not only closely statistically related to each other but also to the components of the metabolic syndrome, suggesting that obesity is indeed a part of this syndrome.

Obesity is caused by a positive energy balance, by either an increased energy intake or a diminished energy output, or both. Both of these factors are regulated by a large number of complicated mechanisms. With the neuroendocrine-endocrine background of the metabolic syndrome, with the HPA axis and cortisol in a central position, one may also ask if the associated obesity might depend on similar factors.

Clinicians know that patients treated with glucocorticoids often become obese with a central localization of excess fat. Such patients often report voracious hunger, which can be objectively observed in clinical wards. Direct experimental measurements in humans show that with administration of glucocorticoids, leptin levels increase (109,110), which would be expected to decrease food intake by induction of satiety. Nevertheless, food intake clearly increases after exposure to elevated glucocorticoid levels, shown recently in fully controlled experiments with a food dispenser (111) or with automatic recording food-monitoring equipment (112).

Animal work shows that after adrenalectomy, food intake is low, such as in the clinical entity of Addison's

disease, and leptin sensitivity is elevated. With graded replacement of corticosterone, leptin sensitivity decreases and food intake increases. With doses of corticosterone, resulting in oversubstitution, food consumption rises, resulting in obesity even with high leptin levels (113). These results show that glucocorticoids can induce leptin resistance, which is characteristic of common human obesity (105). The mechanism for the action of glucocorticoids is apparently not localized to the leptin receptor (114), but may be found in the distal cascade of events after receptor binding.

These results clearly point to the possibility that the HPA axis may also regulate food intake via similar pathways. In addition, recent reports suggest that glucocorticoids might be involved in the stimulation of neuropeptide Y (NPY) secretion (115,116), shifting the NPY-leptin balance toward the former. This information is, however, not consistent and needs amplification.

Taken together (Fig. 9), evidence suggests the possibility that cortisol secretion may in fact be involved not only in the distribution of body fat to central depots, but also may increase total body fat mass by elevated food intake. This area is of considerable interest and should attract further attention. Particularly, long-term studies are needed.

Cortisol is oversecreted after stress challenges. That cortisol may increase food intake raises the question of the existence of the phenomenon of "stress eating." Some people report anecdotally that they eat more when they are stressed, and feel comfort from this, while others report that they lose their appetite. Individuals

**Figure 9** "Stress eating," a hypothesis. Stress induces cortisol secretion, which is followed by increased energy intake in spite of elevated leptin secretion. This results in obesity with an enlarged fraction of body fat in visceral depots (visceral obesity).

subjected to the stress of an impending operation do not increase food intake (117), while schoolgirls seem to do so before examinations (118). Other reports, including animal work, also show mixed results (119,120), and the information in this area is not conclusive. A frequent problem with this research is that the results have relied on subjective reports of both stress and food intake.

A recent report (121) seems to have resolved these problems in an ingenious way. A group of subjects were subjected to standardized laboratory stress tests, and saliva cortisol was measured. Thereafter they were allowed to eat snacks, unaware that the consumption was registered. It then turned out that those who showed elevated cortisol during the stress test also ate more afterward. This study indicates that only when stress results in neuroendocrine reactions is food intake increased, which might explain previous mixed results.

There is thus a good possibility that “stress eating” is indeed a reality and that subjects who show neuroendocrine reactions to stress normally overeat. With time and repeated stress challenges, this would be expected to result in the development of obesity. (Fig. 9). One might therefore consider that the current obesity epidemic is due not only to unlimited availability to energy-dense food and limited need for physical activity but also to current stressful life conditions. The latter may also be involved in eating under time pressure, not allowing time for the perception of satiety signals.

Other hormonal abnormalities in the metabolic syndrome might also be involved in food intake regulation. Low concentrations of sex steroid hormones are known to be followed by obesity (122), and castration is well known to increase fat contents in meat products. This might be a consequence of both increased food intake and a lower physical activity.

Physical inactivity is most likely an important part of the metabolic syndrome (123) and probably contributes to the associated obesity. This may in fact be an important factor for the pathogenesis of the entire syndrome, because physical activity has profound effects on components of the syndrome other than obesity such as insulin resistance, elevated blood pressure and depression (124–126). The direct effects of physical inactivity on the regulation of the HPA axis does not seem to have been studied. Nevertheless, physical inactivity would probably amplify the metabolic syndrome because physical activity counteracts its development and is in fact currently the only globally efficient therapeutic alternative.

In summary, the metabolic syndrome with increase of the visceral fat depots is often combined with generalized obesity. There is a possibility that this is due to

concomitant interference with energy intake regulation by the neuroendocrine disturbance of the syndrome. Physical inactivity is probably an important part of this, because physical activity is an efficient treatment of the syndrome.

## X GENETICS

Genetic susceptibility to develop the metabolic syndrome might be localized to a large number of genes. Since it has been considered unlikely that the components of the syndrome—visceral obesity, insulin resistance, dyslipidemia, and hypertension—can explain the pathogenesis of the entire syndrome, genetic aberrations directly associated with these components will not be discussed. Instead, since it appears that the origin of the metabolic syndrome is found in central regulatory errors, emphasis will be placed on genes involved in such pathways.

### A Aromatase

The aromatase gene may be an important locus for the regulation not only of hyperandrogenicity but also of abdominal obesity with associated metabolic syndrome. In fact, alleles of the microsatellite of the fifth intron of this gene may be important for both the presence of or protection from such symptoms, via short and long alleles respectively. The long, apparently protective allele is found among ~5% of the women in the population we have examined (88). The short allele has previously been reported to be associated with an increased risk for mammary carcinoma and osteoporosis (86,87) and now also with HA (17), which predicts type 2 diabetes, cardiovascular disease, and endometrial carcinoma (11). This, then, is apparently an allele that is associated with a number of serious diseases in women. The androgen receptor gene also seems to be involved with a short microsatellite in the transactivating domain in women with hyperandrogenicity (Baghaei et al., unpublished). Since sex steroid hormones exert powerful effects on central regulation of energy balance (122), these effects may act via central regulatory events. The central regulation of energy balance and HPA axis regulation is very complex. The regulatory events involve, among several additional mechanisms, pro-opiomelanocortin (POMC), corticotropin-releasing hormone, leptin, NPY, the serotonergic, dopaminergic, and adrenergic systems, and insulin, as well as their connections with hormones, neuropeptides, transmitters, and receptors. The relevance for the human sit-

uation is not clear for all these factors. In our first attempts, we have directed attention primarily to the regulation of the HPA axis, the POMC system, leptin, and the neural transmitter systems.

## B Leptin

As discussed above, several polymorphisms in the leptin receptor gene seem to protect against hypertension in obesity (107). A remarkable, unexpected finding in these studies is that these polymorphisms are associated with lower BMI in comparisons with subjects without these polymorphisms (107). With a poorly signaling receptor, one would have expected an elevated BMI. These findings suggest separate pathways for the regulation by leptin of blood pressure and energy intake suppression. In fact, these polymorphisms thus appear to protect against obesity. They are found in 10–25% of the population of men studied (107).

## C The POMC System

The POMC gene produces several hormones, including ACTH, melanocortin, and  $\beta$ -endorphin, all involved in HPA axis and/or energy balance regulation (Fig. 10). A major quantitative trait locus regulating fat mass and leptin production is localized near the POMC gene locus on chromosome 2 (127). Although POMC gene knock-out produces obesity (128), only two obese subjects out of many examined have been identified with a genetic defect in the POMC gene locus (129). A trinucleotide repeat in exon 3, found in 8% of Swedish men, was associated with elevated leptin levels, but without change in obesity measurements (130). This rather infrequent genetic variant then seems to protect against

obesity because it is followed by elevated levels of the satiety hormone leptin.

Alpha-melanocyte stimulating hormone controls energy intake via melanocortin receptors (MCR) 3 and 4 (131,132). Although early studies found only a few associations between polymorphisms in the MCR 4 and obesity (133,134), more recent studies indicate that this is a relatively frequently mutated gene in human morbid obesity (135,136), resembling the phenotype of MCR4 knockout mice (137). A G-to-A substitution in codon 103 (Val103Ile) was found in 3% of Swedish men, and there were 5% G/A heterozygotes but no A/A homozygotes (138). The G/A heterozygotes had lower measurements of abdominal obesity. Saliva cortisol measurements indicated normal kinetics of HPA axis regulation. These findings suggest that the infrequent genetic variant of a G-to-A substitution protects against abdominal obesity.

## D The Serotonergic System

Serotonin (5-hydroxytryptamine, 5HT) exerts major effects on the regulation of both the HPA axis and energy intake and is also involved in mental depression (139). Agents enhancing 5HT availability are used as efficient drugs for the treatment of depression, and have been used as antiobesity agents. Several receptors are identified with different functions (140,141). Serotonin is formed from tryptophan through hydroxylation by the rate limiting enzyme tryptophan hydroxylase. The concentration of 5HT in synapses depends on the rates of formation and reuptake, the latter regulated by the serotonin transporter. The final concentration then acts via several 5HT receptors (5HTR).

Since the 5HT system is involved in both the HPA axis regulation, depression, and energy balance, we considered it of particular interest to study this system in the metabolic syndrome, where all these variables are involved as components or potential etiological factors (2). Several of the observations mentioned in the following are preliminary and result from studies performed in women only (Baghaei et al., unpublished) with the exception of the 5HTR 2A, which has only been examined in men (Rosmond et al., unpublished).

Homozygotes for a short allele in the promoter domain of the tryptophan hydroxylase gene locus show associations to a well functioning HPA axis regulation, but not to obesity variables and their associated metabolic risk factors (unpublished). This variant has a frequency of 37.4%. Homozygotes for a short allele in the promoter domain of the gene locus for the serotonin transporter gene show elevated values of ACTH, free

**Figure 10** Factors regulating food intake. Pro-opiomelanocortin (POMC) induces ACTH and cortisol secretion, regulates the secretion of melanocortin, active via melanocortin receptors (MCR 3 and 4), and  $\beta$ -endorphin.

testosterone, and perturbations in diurnal cortisol secretion, suggesting a hyperactivity of the HPA axis. In addition, elevated abdominal sagittal diameter is an indicator of increased visceral fat mass. This genetic variant is also associated with behavioral characteristics (Baghaei et al., unpublished). It may be speculated that this genetic variation is of importance for the contents of serotonin in nerve synapses, and that the short allele therefore produces the combined effects of both a hyperactive HPA axis and visceral accumulation of body fat. The homozygotes for the short-allele variant have a frequency of ~17%, while homozygotes for the long allele are found in ~33% of cases.

Further results of studies of the serotonin system show in men associations to a genetic variant in the 5HTR 2A with a substitution of G to A at a position in the promoter (–1438). A/A homozygotes have a lower BMI, WHR, and abdominal sagittal diameter, while the G/A genotype shows a diminished suppressibility of cortisol by dexamethasone. The frequencies of the A/A and G/G homozygotes are 33% and 12% (142). It may be speculated that this genetic variation is associated with a product that promotes (G variant) or protects from (A variant) the development of abdominal obesity via serotonin influence on the HPA axis.

Similar studies of the 5HTR 2C in women so far have not revealed any associations of interest (unpublished).

## E The HPA Axis

Finally, along the HPA axis, the gene for corticotropin-releasing hormone (CRH) and the GR gene have been examined. Nothing of interest seems to be present in the CRH gene (Rosmond et al., unpublished), while the GR gene shows several polymorphisms of potential interest. A microsatellite in the first coding exon, containing trinucleotide repeats (CAG), seems preliminary to be of normal length in subjects with the metabolic syndrome (143). A long allele (4.5 kb), obtained by the restriction enzyme Bcl I, cleaving the gene in the first intron, was found to be associated with abdominal obesity, insulin resistance, and hypertension (144–146). We confirmed this and found in addition a poor control of stimulated cortisol secretion (147), suggesting more directly that this polymorphism might be of functional importance for the regulation of the HPA axis. Thirteen percent of Swedish men are homozygotes for this allele, and heterozygotes (45.1%) show similar associations although less powerful. Another polymorphism in the promoter domain was found to be associated with basal cortisol secretion (148). A recent report indicated that a Tsp 5091 polymorphism in the

first coding exon is strongly associated with obesity (149), which, however, we could not confirm (150).

These polymorphisms in the 5' domain of the GR gene are of interest, although their potential functional importance is not known. It might be speculated that genetic variations in the promoter area or in the first intron might be aberrant, with consequences for the function of the GR gene transcript. If this is so, then one has to postulate that there are regional tissue differences in such polymorphisms. If the central GR is affected, then the regulatory feedback control of cortisol secretion would be expected to be inefficient, resulting in exposure of the organism to elevated cortisol levels and the metabolic syndrome. The findings suggest that this might be the correct interpretation because of the apparent association between these polymorphisms and HPA axis regulation (147). If, on the other hand, the peripheral GRs are not functionally optimal, this would presumably protect from excess cortisol effects. Tissue-specific differences in the promoter are known to be present in the GR gene (151). It may also be considered that a deficient function of the central GR, resulting in poor feedback control, may be a secondary effect due to downregulation of receptor density by elevated cortisol secretion (38).

A recent study has shown that the genetic variation in the GR gene, revealed by the Bcl I restriction enzyme, is also associated with the response to overfeeding. Subjects with the 2.3/2.3 kb gene variant were more susceptible to body weight increase as well as elevation of visceral fat mass, plasma lipids, and blood pressure than subjects with the 4.5/2.3 kb genotype (152). This is in apparent contrast to the findings in cross-sectional studies mentioned above, where the 4.5-kb allele was associated with abdominal obesity and other disease risk factors. One might consider that forced overfeeding, in contradiction to spontaneously occurring increase in fat mass, might induce pathological events in a normally regulated system.

The results of these studies are summarized in Table 1. It is apparent that there are a number of polymorphisms in these genes that are associated with the metabolic syndrome and its presumed etiological background in the central neuroendocrine pathways. The data give the impression that the frequency of protective genotypes is rather low in these population studies, at least in the aromatase, POMC, and MCR genes, suggesting that the genes promoting development toward obesity are more prevalent than the gene variants that protect. This might mean that in the general population the genes promoting obesity are more frequent than those that are protective. The

**Table 1** Frequency of Genetic Variants in Central Regulatory Genes Promoting or Protecting from Obesity and the Metabolic Syndrome in Swedish Populations of Middle-Aged Men and Women

| Gene locus      | Protecting allele     | Promoting allele     | % Protecting allele |
|-----------------|-----------------------|----------------------|---------------------|
| Aromatase       | Long microsatellite   | Short microsatellite | 5                   |
| Leptin receptor | Several polymorphisms | Normal               | 10–25               |
| POMC            | Trinucleotide repeat  | No repeat            | 8                   |
| MCR 4           | G→A                   | G/G                  | 3                   |
| TPH             | Short/short           | Long/long            | 37                  |
| SERT            | Long/long             | Short/short          | 33                  |
| 5-HTR 2A        | A/A                   | G/G                  | 33                  |
| GR              | 2.3 kb                | 4.5 kb               | 39                  |

POMC, Pro-opiomelanocortin; MCR 4, melanocortin receptor 4; TPH, tryptophan hydroxylase; SERT, serotonin transporter; 5HTR 2A, 5-hydroxytryptamine receptor 2A; GR, glucocorticoid receptor.

For explanation of alleles, see text.

situation might be different in selected cases of morbid obesity where genetic aberrations have been found in relatively small numbers in the leptin, leptin receptor, and MCR 4 genes.

Moderate obesity and overweight are now very frequent conditions (153). In fact, in several populations, those remaining lean are in the minority, as exemplified by findings in the population of middle-aged women, referred to above, where fewer than one-third have managed to keep their body weight since youth (88). The low prevalence of being lean might be due to selective mechanisms during periods of starvation in prehistoric and historical times, where those with a “thrifty” genotype survived. Such subjects may now constitute a majority of populations, and become obese in the current environment of excess food of high energy density. The minority who are able to remain lean are either restrained eaters or have a genetic predisposition protecting them from obesity. The findings in the population of a low frequency of genes protecting from obesity, as reported above, might therefore be considered to be due to evolutionary selection (154).

## XI SUMMARY, SYNTHESIS, AND CONCLUSIONS

Substantial progress has been made since the previous edition of this chapter in the Handbook of Obesity. The metabolic syndrome is defined in this overview as a clustering of the symptoms insulin resistance, visceral fat accumulation, dyslipidemia, and hypertension. The metabolic syndrome might be considered to originate from a component of the syndrome, particularly when the insulin resistance and the increased visceral fat mass

have been considered. It seems, however, that none of the components can explain the pathogenesis of the entire syndrome. It is difficult to visualize a pathway whereby insulin resistance may explain the accumulation of visceral fat. Visceral fat mass may, via portal free fatty acids, generate at least dyslipidemia and hepatic insulin resistance, but it is hard to understand how hypertension and systemic insulin resistance might be created through this pathway. Furthermore, this reasoning does not explain why depot fat is preferentially accumulated in the “portal” depots in the first place. It may be possible that portal free fatty acids amplify the full expression of the syndrome, but it seems unlikely that this is the primary event in the etiology of the metabolic syndrome.

This opens the possibilities of other primary pathogenic factors. We have since long entertained the possibility that this is a syndrome of central neuroendocrine dysregulations (155), resulting in multiple peripheral endocrine perturbations. The idea originated from the similarities between the metabolic syndrome and Cushing’s syndrome. The major difficulty with this interpretation has been that identification of a functional hyperactivity of the HPA axis is elusive because of technical difficulties in measuring this delicate regulation. These problems are further amplified by the apparent development of different phases in the regulatory error with a first phase of increased cortisol secretion, which then appears to diminish to lower than normal values. In fact, the kinetics of the regulation of the HPA axis seems as important for the associated central and peripheral consequences as total cortisol secretion. This might explain why urinary cortisol secretion seems to be of limited help in disclosing the perturbations. Secondary inhibitions of gonadal and growth hormone axes

contribute to the peripheral perturbations. The mechanisms for the peripheral effects of these endocrine and autonomic perturbations at the tissue, cellular, and molecular levels have been established. It seems somewhat surprising that these pathways have not been studied more extensively to disclose the pathogenesis of risk factors for cardiovascular disease and type 2 diabetes mellitus.

Recent findings are the powerful effects of moderate androgen elevations in women, probably at least partly originating from the adrenals. This might be amplified by a malfunction of the aromatase on a genetic basis. The view on the associations between the anthropometric and metabolic parts of the metabolic syndrome (visceral obesity, insulin resistance, and dyslipidemia) with the hemodynamic part (hypertension) is another new development. First, there is a statistical association between symptoms of the neuroendocrine perturbations and those of the sympathetic nervous system, suggesting that both stress centers are activated in parallel. This is independent of insulin, suggesting that insulin is not involved primarily. The concomitant activation of the HPA axis and the sympathetic nervous system is a well-known phenomenon from stress research. A central activation of the sympathetic nervous system is now an established view on the pathogenesis of primary hypertension. The elevated prevalence of hypertension in the metabolic syndrome might be due to the apparent dependence on leptin signals for blood pressure elevation. Insulin may well also be amplifying the central activity of the sympathetic nervous system.

Our current view on the pathogenesis of hypertension in the metabolic syndrome is therefore that a central activation of the sympathetic nervous system occurs parallel to the activation of the HPA axis, generating respectively elevated blood pressure and metabolic perturbations. The high prevalence of hypertension in the metabolic syndrome is probably due to the additional, amplifying effects of leptin and insulin. This view is strongly supported by similarities in environmental factors activating the HPA axis and the central sympathetic nervous system and thus inducing a frequent or chronic central arousal. With these considerations, the name "metabolic syndrome" may not fit as well, because it consists not only of metabolic symptoms, but also of anthropometric symptoms (visceral obesity) and hemodynamic symptoms (hypertension). It might therefore be time to consider changing the name of this cluster of symptoms to the "central arousal syndrome."

We have long been impressed by the statistical associations of the neuroendocrine, autonomic, and endo-

crine symptoms and their peripheral consequences to psychosocial, socioeconomic, depressive and anxiety symptoms, alcohol consumption, and smoking. The latter phenomena are all known to activate the HPA axis and the central sympathetic nervous system, either via perceived stress reactions or directly, and might therefore be primary etiological factors. These are, however, only statistical associations and need support from intervention studies. Such evidence is now accumulating. First, the Whitehall studies show a close parallelism between a decreasing socioeconomic gradient and the metabolic syndrome, which in our studies can be coupled to HPA axis perturbations and to a time axis of exposure. Furthermore, in prospective studies of the development of hypertension, similar factors are followed by elevated blood pressure. In fully controlled studies in primates, psychosocial stress is followed by all components of the metabolic syndrome, including elevated blood pressure. In addition, depression is connected to the metabolic syndrome in several ways: it can be found in the syndrome in mild, subclinical forms; it is characterized by the same neuroendocrine and autonomic perturbations; and its appearance is followed by the metabolic syndrome, which vanishes when the primary disease is cured.

A most interesting recent development is the apparent overlap in the metabolic syndrome and the small-baby syndrome. Both are characterized by the same neuroendocrine and autonomic perturbations. These seem to develop in the small-baby syndrome by sensitization of central neuroendocrine and autonomic axis due to events during the sensitive periods of brain development in the perinatal period. Originally thought to be due to intrauterine malnutrition, recent developments mainly from experimental animal work have now opened up the possibility that several other factors might be involved, including immune challenges and infections via endotoxins and cytokines. It is too early to state the extent to which perinatal factors are involved in the adult expressions of the metabolic syndrome, although the prevalence of low birth weight in relation to gestational age is currently considerably lower than the prevalence of the metabolic syndrome. This is also the case with the prevalence of HPA axis perturbations in men with low birth weight in relation to such abnormalities found in the adult population. Perinatal factors other than intrauterine malnutrition are most likely involved and need urgently to be defined (Fig. 4).

Recent developments have now opened up the possibility that obesity, defined as increased total body fat mass, is also a consequence of similar events, including HPA axis involvement. This may result in increased

food intake in spite of elevated leptin levels, a condition of "leptin-resistant" obesity, typical for the prevalent human type of obesity. Elevated cortisol seems to have this ability both in controlled animal work and in humans. This increases the credibility of the phenomenon of "stress eating" in certain individuals, and might well contribute to the current epidemic of obesity.

Much of the observed phenomena associated with the metabolic syndrome may disappear with weight reduction, suggesting that obesity is the primary factor, and the neuroendocrine and autonomic phenomena secondary. Intervention studies are useful for interpretation of cause-effect relationships. There are several factors in prospective studies leading to the metabolic syndrome, such as the exposure to different stressful conditions, exposure to exogenous glucocorticoids, and, in women, to androgens, which argue in favor of the interpretation offered in this overview. Furthermore, interventions with testosterone in men or growth hormone in subjects with low secretions are followed by global improvements without necessarily affecting total body fat mass. A critical intervention here would be to normalize the HPA axis regulation, but this has so far not been possible in humans owing to the complex situation. The complications of Cushing's syndrome and glucocorticoid treatment disappear, however, after excluding excess glucocorticoid exposure. This is also the case in animal models exhibiting obesity and the metabolic syndrome.

If obesity is the primary factor, it is difficult to understand why the metabolic syndrome would appear only with visceral obesity and not with peripheral obesity. Furthermore, the associations to environmental factors with handicaps and other phenomena listed above would be difficult to understand, unless they would not also be secondary to obesity. The explanation of the effects on weight decrease on the expressions of the metabolic syndrome is probably that a weight decrease from an obese or nonobese starting point is followed by disruptions of homeostasis in several neuroendocrine and autonomic pathways, which tend to preserve energy. These phenomena appear with or without the presence of obesity or the metabolic syndrome and are probably not involved in the etiology of these conditions. If these counterregulatory mechanisms were known, the obesity treatment would be much more successful.

The elucidation of the phylogenetic expression along the pathways summarized above has made possible molecular genetic studies along these central etiological ways. Associations have been found with several steps in the POMC-MCR-HPA chain of events as well as in the

serotonergic pathway. Several of these findings seem to suggest that a genetic setup preventing obesity is rather uncommon.

Taken together, our original hypothesis, that the metabolic syndrome has its origin in central functional dysregulatory events based on environmental and genetic factors, has been considerably strengthened by continued work in our and other laboratories. The exploration of the function of the HPA axis by the development of new technology has been particularly helpful. The inclusion of the concomitant activation of the central sympathetic nervous system, resulting in hypertension, with the apparent similarities in established background factors, is another important supporting piece of information. Furthermore, independent work showing similarities in the etiology of the metabolic syndrome coming from prospective studies of psychosocially stressed nonhuman primates, socioeconomically stressed humans, mental depression, and the small-baby syndrome all provide support to the hypothesis that the metabolic syndrome has a central origin. Prospective observations indicate that perturbations in HPA axis regulation precede adverse health events. This provides additional strong support for the interpretations of available information as summarized in this overview.

The picture emerging seems to be that the current environment, be it stressful events in a competitive society, exposure to excessive energy-dense food, or physical inactivity, affects mental and bodily systems which are not adapted to such pressures. Outdated survival mechanisms and evolutionary selections are therefore now probably allowed full expression, resulting in the metabolic syndrome in combination with obesity.

### I INTRODUCTION

Until recently, excess weight was generally overlooked as a major risk factor for chronic disease. Now a rapidly expanding body of data is defining the impact of overweight and obesity on premature mortality, cardiovascular disease, type 2 diabetes mellitus, osteoarthritis, gallbladder disease, some types of cancer, and other conditions (Fig. 1) (1,2). Models using data from the Third National Health and Nutrition Examination Survey (NHANES III), the Framingham Heart Study, and other sources have demonstrated a direct, dose-dependent relationship between increasing body mass index (BMI) and lifetime risk of various conditions (Table 1) (3–5). Data from the U.S. Behavioral Risk Factor Surveillance System indicate that obesity is associated with greater morbidity and poorer health-related quality of life than smoking or problem drinking (6), and a recent conservative estimate, derived from five long-term prospective cohort studies, suggests that overweight and obesity account for >280,000 deaths each year in the United States (7). The substantial morbidity and mortality associated with excess

weight underscore the pressing need to improve the education of health professionals and the public about the hazards of overweight and obesity and to remove the barriers to healthy eating and increased physical activity.

### II MORTALITY

While the precise shape of the body weight/mortality curve remains controversial, there is little question that substantial excess adiposity increases mortality. A reanalysis of 12-year follow-up data of the American Cancer Society's Cancer Prevention Study I cohort that excluded smokers and those with a history of cancer or cardiovascular disease at baseline (8), as well as a new analysis of a second Cancer Prevention cohort of more than 1 million adults with 14 years of follow-up (9), showed a clear pattern of increasing mortality with increasing weight (Fig. 2). Among healthy people who had never smoked, optimal mortality was found at a BMI of 23.5–24.9 for men and 22.0–23.4 for women. These data confirm similar observations from a 27-year

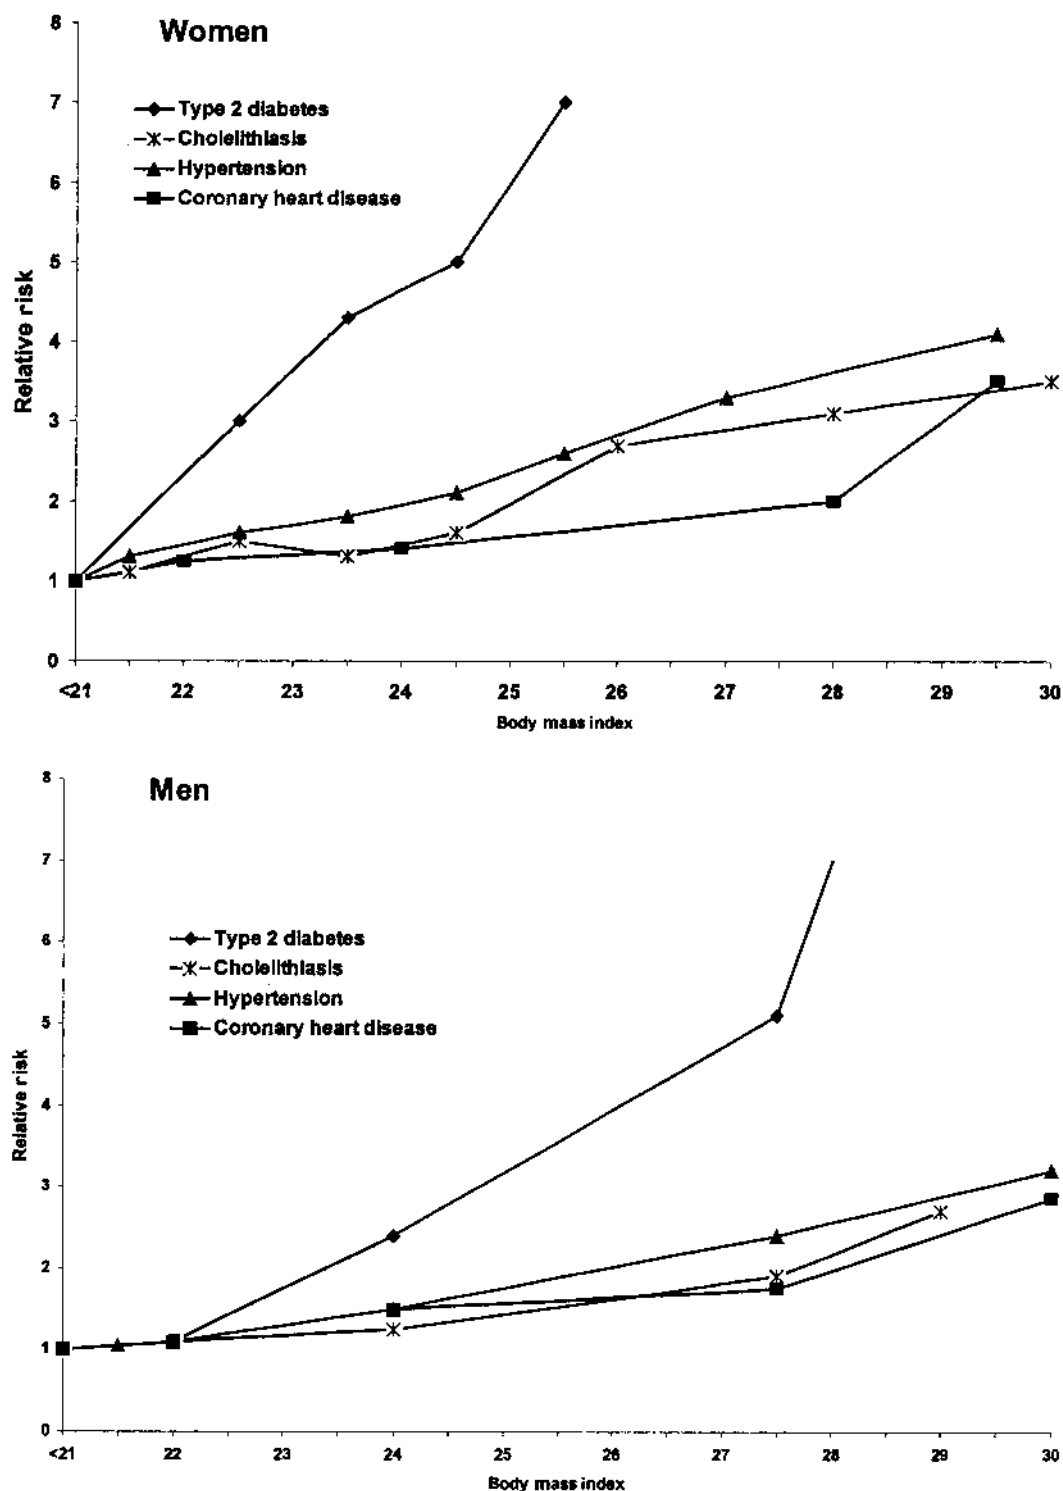

Figure 1 Relation between body mass index up to 30 and the relative risks of type 2 diabetes, cholelithiasis, hypertension, and coronary heart disease in the Nurses' Health Study and the Health Professionals Follow-up Study. (From Ref. 13.)

follow-up of more than 19,000 middle-aged men in the Harvard Alumni Study (10), a 16-year follow-up of 115,000 middle-aged female nurses (11), and a 12-year follow-up of nonsmoking Seventh-Day Adventists (12). Using data from five long-term prospective cohort studies, Allison and colleagues estimated the annual number of adult deaths in the United States attributable to obesity at 280,000 per year (7), making obesity second only to tobacco as a cause of preventable death in the United States.

Although some investigators have argued that the optimal weight increases with age, this observation is probably an artifact of the increasing prevalence of weight loss secondary to chronic disease and comorbidity among older individuals, the cumulative effects of cigarette smoking, and the reduced reliability of BMI as a measure of adiposity with advancing age (13). Reports from the Framingham Heart Study (14), the Adventist Health Study (15), and the American Cancer Society (8) cohorts indicate that, although the strength of the association between body weight and mortality

decreases with age, being overweight remains predictive of excess mortality and that at least up to age 75, a BMI <25 kg/m<sup>2</sup> is associated with reduced total mortality.

### III CARDIOVASCULAR DISEASE

Although obesity has been linked with cardiovascular disease for centuries, it was only formally recognized as a major modifiable coronary risk factor in 1998 (16). As described below, and in greater detail in subsequent chapters, obesity is associated with increased risks of coronary heart disease, stroke, venous thromboembolism, congestive heart failure, and cardiomyopathy. Obesity increases these risks partly through its effects on established coronary risk factors such as hypertension, dyslipidemia, and insulin resistance, as well as its effects on novel risk factors such as thrombotic and inflammatory markers. For example, in the Marks and Spencer Cardiovascular Risk Factor Study of 14,077 middle-aged women, highly significant age-adjusted

**Figure 2** Multivariate relative risk of death from all causes among men and women according to body mass index, smoking status, and disease status, using subjects with a body mass index of 23.5–24.9 kg/m<sup>2</sup> as the referent. (From Ref. 9.)

changes were observed across seven categories of BMI (<20 to  $\geq 30$  kg/m<sup>2</sup>) for systolic and diastolic blood pressure, serum total cholesterol, high-density lipoprotein (HDL) cholesterol, low-density lipoprotein (LDL) cholesterol, triglycerides, and fasting blood glucose (17). Excess weight is also associated with increases in thrombotic markers such as fibrinogen and plasminogen activator inhibitor-1, as well as increases in inflammatory markers such as C-reactive protein, that have been associated with increased risk of cardiovascular disease and diabetes (18–20). Consistent with the excess risk of coronary heart disease even among

individuals with average weights, the Framingham Heart Study has demonstrated that many individuals with BMIs between 23 and 25 kg/m<sup>2</sup> have abnormalities in serum lipids, glucose tolerance, and blood pressure compared to those with BMIs <23 kg/m<sup>2</sup>, and most individuals with BMIs >25 kg/m<sup>2</sup> have such abnormalities. In addition to its effect on these cardiovascular risk factors, obesity appears to have an independent effect on cardiovascular risk, suggesting the existence of additional mechanisms.

Limited data are available regarding the long-term benefits of intentional weight loss on cardiovascular risk. However, a number of mostly small clinical trials of varying design demonstrate benefits of weight loss among overweight and obese individuals on specific cardiovascular risk factors, including blood pressure, glucose tolerance, and lipoprotein profile, that would be expected to lower cardiovascular risk (21).

### A Coronary Heart Disease

Numerous observational studies, including many long-term prospective cohort studies (22–32), have demonstrated a direct association between excess weight and coronary heart disease, the most common cause of death in the United States. The relationship appears to be linear, and even individuals of average weight (i.e., those with BMIs of 24–26 kg/m<sup>2</sup>) at midlife are at increased risk compared with leaner individuals. In the Nurses' Health Study, for example, even after controlling for age, smoking, menopausal status, use of postmenopausal hormones, and parental history of myocardial infarction, the relative risk of coronary heart disease was 1.2 (95% CI, 0.97–1.44) for women with BMIs of 21–22.9 kg/m<sup>2</sup>, 1.46 (95% CI 1.20–1.77) for BMIs of 23–24.9 kg/m<sup>2</sup>, 2.06 (95% CI, 1.72–2.48) for BMIs of 25–28.9 kg/m<sup>2</sup>, and 3.56 (95% CI, 2.96–4.29) for BMIs of 29 kg/m<sup>2</sup> or more, compared with women whose BMIs were <21 kg/m<sup>2</sup> (33). Weight gain after age 18 was also associated in a dose-dependent fashion with increased risk of coronary heart disease. When women who had lost or gained less than 5 kg were used as the referent, the risk of coronary heart disease was 1.65 (95% CI, 1.33–2.05) among those who gained 8–10.9 kg, 1.92 (95% CI, 1.61–2.29) among those who gained 11–19 kg, and 2.65 (95% CI, 2.17–3.22) among those who gained  $\geq 20$  kg (33). A 26-year follow-up of more than 5000 men and women in the Framingham Heart Study showed that relative weight at baseline was positively associated with coronary heart disease, coronary mortality, and congestive heart failure independent of age, cholesterol level, systolic

blood pressure, smoking, and other cardiovascular risk factors (34). As in the Nurses' Health Study, weight gain after young adulthood was associated with increased risk of cardiovascular disease in both men and women.

In addition to the amount of fat, the pattern of fat deposition may also influence cardiovascular health. Adipose tissue in the waist, abdomen, and upper body is more metabolically active than that in the hip, thigh, or buttocks (35), and abdominal fat accumulation appears to be an important predictor of dyslipidemia, hypertension, and coronary heart disease, as well as of type 2 diabetes. The increased sensitivity of abdominal fat cells to lipolytic stimuli and the subsequent direct delivery of fatty acids and glycerol to the liver, thus inducing insulin resistance, are possible pathophysiologic explanations for these observed associations. Abdominal adiposity can be estimated using waist circumference or waist-to-hip ratio. A waist-to-hip ratio  $>0.80$  in women or  $>0.95$  in men is predictive of a substantially increased risk of cardiovascular disease (36,37). Similarly, a waist circumference of  $\geq 35$  inches in women or  $\geq 40$  inches in men is associated with increased vascular risk.

## B Stroke

The clear weight-related increases in blood pressure, lipids, and blood glucose described above should be expected to translate into an increased risk of stroke. However, data regarding this association are less consistent than they are for coronary heart disease. Among male health professionals, abdominal adiposity but not BMI was related to stroke risk (38), while among female nurses, BMI and weight gain were strongly associated with increased risk of total and ischemic stroke, but not hemorrhagic stroke (39). Among Japanese men, subscapular skinfold thickness but not BMI or abdominal adiposity was related to stroke risk (40). And a recent report from the Physicians' Health Study found that increasing BMI increased the risks of total, ischemic, and hemorrhagic stroke (41). To date, there are no data from prospective studies regarding reduction in stroke risk with weight loss.

## C Venous Thromboembolism

Studies of the risk factors for venous thromboembolism, which have largely been conducted among populations of hospitalized patients, have generally demonstrated an association between excess weight and deep-vein thrombosis or pulmonary embolism

(42). Two prospective studies support this association. Among female nurses, the relative risk of developing primary pulmonary embolism over 14 years of follow-up was 2.9 (95% CI, 1.5–5.4) among those with BMIs of  $29 \text{ kg/m}^2$  or greater compared with those whose BMIs were  $<21 \text{ kg/m}^2$  (43). In the Swedish study of men born in 1913, among participants in the highest decile of waist circumference ( $\geq 100 \text{ cm}$ ) the adjusted relative risk of experiencing a deep-vein thrombosis or pulmonary embolism over 26 years of follow-up was 3.92 (95% CI, 2.10–7.29) compared with men with a waist circumference  $<100 \text{ cm}$  (44).

## IV TYPE 2 DIABETES MELLITUS

Excess weight plays a critically important role in the etiology of type 2 diabetes mellitus (see Chap. 39). Obesity, especially central obesity, causes insulin resistance and compensatory hyperinsulinemia, which are involved in the development of type 2 diabetes (45). Data from NHANES III show a direct association between BMI and prevalence of type 2 diabetes among adults (Fig. 3) (2).

Associations between BMI and risk of type 2 diabetes have been observed in diverse populations, including female nurses (46), male health professionals (47), Mexican-Americans (48), Pima Indians (49), and Japanese railway employees (50). In the Health Professionals Follow-up Study, which included more than 50,000 middle-aged men, the relative risk of developing type 2 diabetes over 5 years of follow-up was 42 times higher in men with BMIs of  $35 \text{ kg/m}^2$  or higher than among those with BMIs  $<23 \text{ kg/m}^2$  (47); when men with BMIs  $<25.0 \text{ kg/m}^2$  were used as the referent, the relative risk was 3.5 (95% CI, 2.9–4.1) for those with BMIs of  $25.0$ – $29.9 \text{ kg/m}^2$ , 11.2 (95% CI, 9.3–13.6) for those with BMIs of  $30.0$ – $34.9 \text{ kg/m}^2$ , and 23.4 (95% CI, 19.4–33.2) for those with BMIs of  $35.0 \text{ kg/m}^2$  or greater (51). In the Nurses' Health Study, the relative risk of developing type 2 diabetes over 10 years of follow-up was 4.6-fold higher among women with BMIs of  $25.0$ – $29.9 \text{ kg/m}^2$  than among those with BMIs  $<25.0 \text{ kg/m}^2$ , 10-fold higher among those with BMIs of  $30.0$ – $34.9 \text{ kg/m}^2$ , and 17-fold higher among those with BMIs of  $35.0 \text{ kg/m}^2$  or greater (51). In both of these studies, weight gain during adulthood was strongly associated with increases in risk of developing type 2 diabetes.

Given the widespread prevalence of diabetes—more than 15 million cases in the United States and 154 million cases worldwide (52)—even small reductions

**Figure 3** Prevalence of type 2 diabetes in the Third National Health and Nutrition Examination Survey by BMI categories. (From Ref. 2.)

in risk could have important effects on the global burden of this disease. Several recent studies suggest that weight loss, either alone or combined with physical activity, improves glucose levels and insulin action among individuals with type 2 diabetes (53) and lowers the risk of diabetes among overweight individuals (54). In the randomized Finnish Diabetes Prevention Study, conducted among 522 middle-aged, overweight men and women with impaired glucose tolerance, the risk of developing diabetes over 3.2 years of follow-up decreased 58% among those assigned to intervention (weight loss, improved nutrition, and increased physical activity) compared to the control group assigned to usual care (55). Bariatric surgery also appears to provide long-term control of type 2 diabetes among morbidly obese patients (56). A randomized trial funded by the National Institute of Diabetes and Digestive and Kidney Diseases, the Look AHEAD (Action for Health in Diabetes) trial, is under way to examine the effects of a lifestyle intervention designed to achieve and maintain weight loss over the long term through decreased caloric

intake and increased exercise among 5000 obese individuals with type 2 diabetes (57). Results from this trial should also offer important insights into the potential beneficial effects of weight loss on risk of cardiovascular disease and other chronic conditions.

## V CANCER

Ever since the landmark American Cancer Society cohort study of 750,000 U.S. adults found a highly significant age- and smoking-adjusted 33% increased risk of cancer death among obese men and a 55% increase among obese women (58), hundreds of other studies have examined the association between weight and cancer in greater detail. Most, but not all, of these studies suggest that excess weight is associated with increased risks of endometrial (59), postmenopausal breast (59), kidney (60), gallbladder (61), and colon (62) cancers. A recent meta-analysis of overweight and cancer in Europe suggests that excess weight accounts for 3.4% of cancers in men and 6.4% in women, or a total of

72,000 cases of cancer in Europe (63). By cancer site, the population attributable risk for excess weight was 39% for endometrial cancers, 25% for kidney cancers, 24% for gallbladder cancers, and 11% for colon cancers.

## VI LIVER AND GALLBLADDER DISEASE

Obesity is commonly associated with morphological and functional changes in the liver. In one autopsy study, nonalcoholic steatohepatitis, a pathological condition characterized by fatty infiltration, inflammation, and fibrosis, was observed in 18.5% of markedly obese patients and 2.7% of lean patients; severe fibrosis was found in 13.8% of markedly obese patients and 6.6% of lean patients (64). Other series suggest that 70% or more of patients with nonalcoholic steatohepatitis are overweight (65). Although nonalcoholic steatohepatitis is generally a benign disease, patients with this condition occasionally develop cirrhosis, portal hypertension, and hepatic failure.

The risk of developing gallstones also increases with increasing weight, with a four-to-fivefold higher prevalence among those with BMIs of 40 kg/m<sup>2</sup> or higher compared with individuals with BMIs between 18.0 and 24.9 kg/m<sup>2</sup> (5). Among female nurses, the adjusted relative risk of cholecystectomy or new-onset gallstones was 6.0 (95% CI, 4.0–9.0) for obese women with BMIs of 32 kg/m<sup>2</sup> or greater and 1.7 (95% CI, 1.1–2.7) for women with BMIs of 24.0–24.9 kg/m<sup>2</sup>, compared with women whose BMIs were <20 kg/m<sup>2</sup> (66). When women with BMIs of <25.0 kg/m<sup>2</sup> were used as the referent, the relative risks were 1.9 (95% CI, 1.7–2.0) for women with BMIs of 25.0–29.9 kg/m<sup>2</sup>, 2.5 (95% CI, 2.3–2.7) for those with BMIs of 30.0–34.9 kg/m<sup>2</sup>, and 3.0 (95% CI, 2.7–3.3) for those with BMIs of 35.0 kg/m<sup>2</sup> or greater (51). An analysis from the same cohort suggested that weight cycling was also highly associated with risk of cholecystectomy, independent of BMI (67).

## VII OSTEOARTHRITIS

Arthritis is one of the leading causes of disability among U.S. adults over age 15 (68). Osteoarthritis of the knee, hip, and hand account for much of this disability among older individuals. Data from NHANES III indicate that the prevalence of osteoarthritis among women increases with increasing body weight, from 52/1000 women with BMIs between 18.0 and 24.9 kg/m<sup>2</sup> to 172/1000 for those with BMIs >40 kg/m<sup>2</sup> (Fig. 4) (5). Data for men

show a similar trend. This association is most likely due predominantly to mechanical stresses on weight-bearing joints (see Chap. 42).

In the Framingham Osteoarthritis Study, among 1420 participants who had radiographs of the knee taken during a routine biennial follow-up, 468 had evidence of osteoarthritis. The relative risk of osteoarthritis was twofold higher among obese women and 1.5-fold higher among obese men than among lighter individuals (69). A similar increased risk of osteoarthritis of the knee has been observed in other cohort (70–73), twin (74), and national survey (75,76) studies. The association between obesity and osteoarthritis of the hip is less strong, with some studies showing a positive association (77–79) and others showing no association (70,73).

A recent pilot trial of exercise and weight loss among 24 elderly obese men and women showed significant improvements in pain, performance, and disability (80). Weight loss alone, achieved through diet (81), pharmacotherapy (82), or surgery (83), has also been associated with reductions in osteoarthritis-related symptoms.

## VIII SLEEP APNEA

Excessive fat in the pharyngeal area, chest wall, and abdomen can profoundly alter pulmonary function via adverse effects on respiratory mechanics, respiratory muscle function, lung volume, and upper-airway narrowing (see Chap. 41).

Sleep apnea, defined as a cessation of air flow for 10 sec or longer during sleep, is a common consequence of obesity, particularly among men. More than half of men and one-third of women in the Swedish Obese Subjects Study reported snoring and apnea (84), compared with 4% of men and 2% of women in general populations (85). In the Wisconsin Sleep Cohort Study, increasing weight was a significant risk factor for sleep apnea, with a 10% increase in weight associated with a sixfold increase in the risk of developing moderate to severe sleep-disordered breathing (86).

Many patients with sleep apnea have excessive daytime sleepiness. In addition, recent epidemiologic studies have demonstrated that sleep apnea is a risk factor for hypertension (87) and may lead to the development of cardiovascular disease. In the Sleep Heart Health Study, for example, sleep-disordered breathing was significantly associated with increased risks of heart failure, stroke, and coronary heart disease (88). Weight loss significantly alleviates sleep apnea and improves nighttime breathing (86,89).

**Figure 4** Prevalence of osteoarthritis among women in the Third National Health and Nutrition Examination Survey by BMI categories. (From Ref. 5.)

## IX REPRODUCTIVE HEALTH

Obesity during pregnancy is related to increased morbidity for both mother and child (see Chap. 43). Maternal obesity is associated with a 10-fold increased risk of hypertension and a threefold increased risk of gestational diabetes (90,91), and is also strongly associated with the risk of pre-eclampsia (92,93). Women who are overweight or obese are also more likely to have other complications of pregnancy than women in the healthy weight range. In an analysis of more than 96,000 births in Washington state, for example, overweight and obese women were significantly more likely to have preterm deliveries, to deliver babies heavier than 4000 g, or to require caesarean section, and infants born to obese women had a twofold increased risk of death within the first year of life (94). Obesity also increases the risks associated with anesthesia, possibly due to the technical difficulties in administration (95). Excess weight may also interfere with the ability to become pregnant. Among female nurses, BMI at age 18 was strongly associated with subsequent risk of ovula-

tory infertility in women with and without a diagnosis of polycystic ovary syndrome, ranging from a relative risk of 1.3 among women with BMIs of 24–25.9 kg/m<sup>2</sup> to 2.7 among women with BMIs of 32 kg/m<sup>2</sup> or greater, compared with those with BMIs of 20–21.9 kg/m<sup>2</sup> (96).

Obesity-related risks may be borne by the developing fetus as well, with studies suggesting associations between maternal obesity and increased risk of neural tube defects (97) and other congenital malformations (98).

## X QUALITY OF LIFE

Another measure of the cumulative burden of weight-related disorders is quality of life. In analyses from the Nurses' Health Study, both higher BMI and substantial weight gain during adulthood were strongly associated with reduced daily physical functioning and vitality, a greater burden of physical pain, and diminished feelings of well-being. The average decline in physical function experienced by a woman under age 65 years

who gained 9 kg or more over a 4-year period was approximately three times the magnitude of that associated with cigarette smoking over the same period (99,100). In NHANES III, the proportion of participants reporting excellent health decreased in a linear fashion with increasing BMI among whites, blacks, and Hispanics, even in the absence of chronic disease conditions (101).

## XI CONCLUSION

In the United States and other developed countries, the prevalence of many cardiovascular risk factors is declining. Smoking rates, average cholesterol levels, and the prevalence of hypertension in the United States have fallen significantly since the 1960s (102). At the same time, however, the prevalence of overweight and obesity continues to rise and is reaching epidemic proportions in both developed and developing countries. Given the strong associations between obesity and cardiovascular disease, type 2 diabetes, and other chronic diseases, this trend portends an enormous global burden of obesity-related morbidity and mortality in the century ahead.

Public health approaches such as those used to educate the public about the dangers of smoking, high cholesterol, and high blood pressure must be adapted for the prevention and control of overweight and obesity. In addition, health professionals must play a more active role in counseling overweight and obese patients about the health hazards of excess weight and in prescribing and encouraging sustained changes in behavior that can lead to a healthier weight. Guidelines developed by the National Heart, Lung and Blood Institute in conjunction with the North American Association for the Study of Obesity offer concrete advice for clinicians regarding the evaluation and treatment of obesity (1). Given the prevalence of overweight, helping even a small percentage of overweight or obese patients achieve a healthy weight would have a substantial impact on public health, as would helping those already in the healthy weight range maintain their weight.

### I INTRODUCTION

Cardiovascular disease is the leading cause of death in industrialized countries, and in the United States, cardiovascular disease accounts for ~50% of all deaths (1). Obesity increases risk for coronary heart disease (CHD), congestive heart failure (CHF), arrhythmia, sudden death, and several other cardiovascular diseases (Table 1). Obesity promotes several traditional risk factors for cardiovascular disease, and in addition considerable attention has been devoted to defining the pathogenic role of excess weight that is independent of traditional risk factors. Obesity has recently been found to be associated with several nontraditional risk factors, such as disturbances in fibrinolysis, impaired endothelial function, and chronic low-grade inflammation. Regardless of the mechanism, it is clear that obesity is associated with deleterious effects on the heart and circulatory system.

In the sections below, the increased demands imposed by obesity on the heart and circulation and the resultant cardiovascular adaptation are reviewed. This is followed by discussion of the contribution of obesity to pathologic conditions such as CHF, arrhythmia, CHD, and other cardiovascular syndromes. The beneficial effects of weight loss on specific conditions and overall cardiovascular mortality is also discussed where

evidence exists. Finally, the association between weight loss medications and cardiac valve disease, as well as cardiovascular effects of other appetite suppressants, is presented.

### II EFFECTS OF OBESITY ON CARDIAC STRUCTURE AND FUNCTION

Obesity is characterized by expansion of fat mass, as well as expansion of skeletal muscle, viscera, and skin, all of which increase oxygen consumption (2,3). Although metabolically active, adipose tissue oxygen consumption is lower than for lean tissue, hence total body oxygen consumption expressed per kilogram of body weight in the obese is lower than in leaner persons (3–5). Obesity is also accompanied by expansion of extracellular volume, which comprises the intravascular and interstitial fluid spaces. Total blood volume and plasma volume generally increase in proportion to the degree of overweight (4,6–8). For example, in comparison to lean control groups (BMI 22 kg/m<sup>2</sup>), nonhypertensive obese subjects (BMI ~36 kg/m<sup>2</sup>) had 20–25% expansion of total blood volume, while the ratio of central to total blood volumes was comparatively unchanged (7,8). Expansion of blood volume leads to increased left ventricular filling, which in turn results in

**Table 1** Cardiovascular Diseases Associated with Obesity

|                              |
|------------------------------|
| Coronary heart disease       |
| Stroke                       |
| Hypertension                 |
| Left ventricular hypertrophy |
| Congestive heart failure     |
| Sudden death                 |
| Arrhythmia                   |
| Deep-vein thrombosis         |
| Pulmonary embolus            |
| Venous insufficiency         |

increased stroke volume (6,9–11). The increase in cardiac output is generally in proportion to excess weight, reflecting the interrelationships among weight, blood volume, stroke volume, and cardiac output (4,6,7,9,12). Heart rate, the other determinant of cardiac output, remains essentially unchanged and does not significantly contribute to increased cardiac output in obesity (4,6,7,10,11). While cardiac output is increased in absolute terms, when normalized to body surface area, values remain in the normal range (4,7). Arteriovenous oxygen extraction, another mechanism that could increase oxygen delivery, is unchanged or only slightly increased in obesity (5,9).

Reduced systemic vascular resistance accompanies elevations in cardiac output that occur in nonhypertensive obesity (4,5,7). This reduction in peripheral resistance in part explains why hypertension is not observed in all obese individuals who have elevated intravascular volume and cardiac output. A limitation to this adaptive mechanism clearly exists, however, since hypertension is commonly associated with obesity.

The initial response to increased metabolic demand and total blood volume is increased left ventricular filling, leading to chamber dilatation and increased cardiac output. However, longer-term structural changes accompany this hemodynamic adaptation. Left ventricular dilatation increases myocardial wall stress, which, over time, stimulates left ventricular myocardial growth and leads to elevated mass. In turn, wall stress is normalized, diminishing (at least in part) the stimulus for further hypertrophy. In cross-sectional observations, ventricular mass has been increased in proportion to BMI, degree of overweight or fat mass (11,13–17). In a recent trial, left ventricular mass was associated with fat mass, but was more strongly associated with fat-free mass (18), perhaps reflecting the greater relative contribution of fat-free mass than fat mass to oxygen consumption. In addition to degree of obesity, duration of obesity also appears to be predictive of left ventricular

mass (15). Left ventricular mass has been directly associated with measures of central obesity, but the strengths of these associations have varied considerably between studies (11,14,18,19). Wikstrand et al. (11) have proposed that central obesity does not have an independent effect on ventricular mass, but may promote adverse loading conditions or elevated blood pressure. Metabolic factors associated with central obesity, such as insulin resistance and hyperinsulinemia (20), have also been proposed to contribute to left ventricular hypertrophy. Right ventricular dilatation and hypertrophy also have been observed in extreme obesity (21), and the presence of obstructive sleep apnea or obesity hypoventilation syndrome appears to increase risk for right as well as left ventricular hypertrophy (22).

When left ventricular dilatation and hypertrophy occur together, the usual relationship between left ventricular cavity radius and wall thickness is preserved and eccentric hypertrophy results (Fig. 1). Hypertension also promotes hypertrophy, reflecting the increased wall stress associated with elevations in systemic vascular resistance. Essential hypertension in lean patients is, in contrast to obese patients, typically characterized by

**Figure 1** Effect of obesity and hypertension on cardiac structure. (Adapted from Ref. 238.)

intravascular volume contraction and elevated systemic vascular resistance (4,7,23). In obese hypertensives, the effects on blood volume expansion and systemic vascular resistance reflect either a balance of the two stimuli or favor the predominant process (7,8). In obese hypertensives, effects on ventricular mass and dimensions are independent and additive, and left ventricular mass is greater in obese hypertensives than in obese normotensives (16,17,24,25). Since intravascular volume is contracted, ventricular wall thickness due to hypertrophy is increased disproportionately to the chamber radius, resulting in a decreased ratio of chamber radius to wall thickness, or concentric hypertrophy. The separate and combined effects of obesity and hypertension on the left ventricle are depicted in Figure 1.

Autopsy studies assessing cardiac structure and pathology have been mostly limited to those who were extremely obese, which is in contrast to the studies above which assessed subjects representing a wider spectrum of leanness to obesity and employed echocardiography or other noninvasive methods. Early autopsy study by Smith and Willius (26) in 135 obese patients who died of congestive heart failure revealed a direct relationship between body weight and heart weight. Fatty infiltration of the heart (extension of epicardial fat into the myocardium and perivascular region) was also noted, leading to speculation that increased heart weight and pathology were due to fatty infiltration. Carpenter (27) subsequently observed fatty infiltration in ~3% of obese subjects at autopsy. Fatty infiltration occurs in several other disease states, including malnutrition, and despite its presence in obesity, is no longer believed to underlie most cardiac pathology in obesity (9,12). In another autopsy study, Amad et al. (28) examined the relationship between body weight and heart weight in 12 severely obese subjects without hypertension or coronary artery disease. Heart weight was far in excess of that predicted for ideal body weight, gross ventricular hypertrophy was present, and on microscopic examination the cause was noted to be myocardial hypertrophy. Other autopsy studies have noted increased left ventricular chamber size and mass associated with obesity, confirming that eccentric hypertrophy is the primary cause of increased heart weight (9).

### III LEFT VENTRICULAR HYPERTROPHY AND CONGESTIVE HEART FAILURE

#### A Left Ventricular Hypertrophy

Left ventricular hypertrophy is an adaptive but not an entirely benign response. Left ventricular hypertrophy has been associated with greater risk of cardiovascular

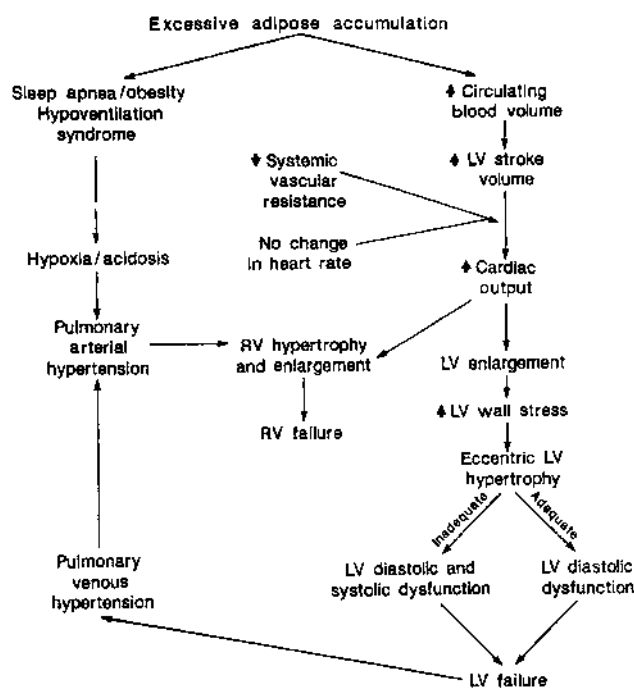

morbidity and all-cause mortality, CHD, congestive heart failure, arrhythmia, and sudden death (29–35). Such effects appear to be independent of traditional risk factors for cardiovascular disease such as hypertension, blood lipids, and existing CHD (29–34). In a minority of trials, effects of eccentric hypertrophy have been differentiated from those of concentric hypertrophy. Koren et al. (29) assessed mortality and cardiovascular events in 253 hypertensive patients (mean age 47 years) who had been evaluated by echocardiogram an average of 10 years previously. Patients were classified as having normal left ventricular mass, or concentric ( $n = 29$ ) or eccentric ( $n = 40$ ) left ventricular hypertrophy, but no information regarding obesity within each group was provided. For the whole population, left ventricular mass index (left ventricular mass/body surface area) predicted cardiovascular events or death better than several traditional risk factors. Those with baseline concentric hypertrophy experienced the greatest number of cardiovascular deaths and events (21% and 31%), while eccentric hypertrophy was intermediate (10% and 23%), and absence of hypertrophy demonstrated the lowest frequencies (0% and 11%). Gardin et al. (35) followed 5888 men and women (mean age 73 years) for 6–7 years and found that left ventricular mass at baseline was significantly higher in those with incident CHD, CHF, stroke (women only), and all-cause mortality (men only). A significant trend for incident CHD and CHF was observed across quartiles of left ventricular mass, and in those with eccentric hypertrophy the hazards ratio for incident CHD and CHF were 2.05 (95% CI 1.16–3.32) and 2.95 (95% CI 1.56–5.57). Thus, left ventricular hypertrophy is clearly associated with increased cardiovascular disease, although the specific relationships between left ventricular hypertrophy and geometry and cardiovascular outcomes in obese patients require further definition.

#### B Congestive Heart Failure

When the hypertrophic response is commensurate to left ventricular dilatation, filling pressures and wall stress are normalized by increased ventricular mass, and systolic function is maintained (12). Even when systolic function is maintained, however, left ventricular diastolic dysfunction may occur (15,36–38). Diminished ventricular compliance results in impaired accommodation of volume during diastole, resulting in diastolic dysfunction (15,36–38). Factors associated with diastolic dysfunction include degree and duration of overweight, degree of volume expansion, and adverse loading conditions imposed by volume overload or hypertension (15,25,36). Diastolic dysfunction may be

evident on the resting echocardiogram, but may not become clinically evident until provoked by volume overload or exercise. Frank congestive heart failure due to diastolic dysfunction does occur but is most often observed in extreme obesity, and echocardiography or angiography may be needed to differentiate between underlying diastolic and systolic dysfunction (9).

When left ventricular filling exceeds favorable loading conditions and hypertrophy does not keep pace to normalize resultant wall stress, ventricular contractility is impaired and systolic dysfunction ensues (12). This is illustrated on echocardiogram as an increase in the ratio of the left ventricular cavity radius relative to wall thickness (9,12). Further evidence of systolic dysfunction was provided by two trials that demonstrated that left ventricular ejection fraction decreased inversely with BMI as well as duration of overweight (6,15). Systolic dysfunction does not occur universally in obesity, but appears to be a function of the degree and duration of overweight as well as adverse loading conditions (5,6,15,39). These and other factors that potentially contribute to the progression from physiologic adaptation and compensation, to diastolic and systolic dysfunction, and to frank decompensation, are illustrated in Figure 2.

**Figure 2** Pathophysiology of adaptation and congestive heart failure in obesity. (Adapted from Ref. 12.)

Evidence for an association of obesity with CHF is found in observational, clinical, and clinicopathologic trials. Body weight, independent of several traditional risk factors, was directly related to development of congestive heart failure in the Framingham Heart Study (40). In that study, incidence of congestive heart failure in those >130% of Metropolitan Relative Weight was almost twice that of subjects <110%. In the National Health and Nutrition Examination I follow-up study, overweight was associated with a modestly increased risk of developing congestive heart failure (RR 1.35, 95% CI 1.17–1.55,  $P < .001$ ), which was only slightly weakened and remained significant when included in a multivariate model with CHD, diabetes, smoking, hypertension, and diabetes (41). In extremely obese patients, Alpert et al. (42) found that duration of obesity was strongly related to the presence of CHF. In a recent assessment of 159 consecutive patients referred for echocardiogram for congestive heart failure, 109 had preserved systolic function, and 40 of these 109 had a BMI  $\geq 30$  kg/m<sup>2</sup> (43). Kasper and colleagues (44) performed endocardial biopsy on lean and overweight patients with clinically evident dilated cardiomyopathy to assess the etiology of heart failure. Specific pathologic diagnoses were evident in 64% of the patients with BMI < 30 kg/m<sup>2</sup>, while in those patients with BMI > 35 kg/m<sup>2</sup> no specific tissue diagnosis could be made in 77%, suggesting that obesity may have been the primary etiologic factor.

### C Effects of Weight Loss on Cardiac Structure and Function

Weight loss is accompanied by decreases in oxygen requirements, blood volume, and cardiac output (45–47). Reductions in blood pressure occur early in weight loss and with modest amounts of lost weight (45,48–50), while greater degrees of weight loss have resulted in amelioration or resolution of severe hypertension (51–53). Given trends toward normalization of blood volume and blood pressure, parallel changes in cardiac function and structure might be expected. In mildly to moderately obese persons, weight loss in the range of 4–10 kg has only inconsistently been associated with decreased left ventricular dimension, loading conditions, and systolic function (54–60). Despite the lack of consistency in hemodynamic and functional parameters, reductions in left ventricular mass or wall thickness were observed in all but one (59) of these trials and appeared to occur independent of reductions in blood pressure (56,57). To differentiate between the effects of lost weight and reductions in blood pressure in over-

weight hypertensive subjects, MacMahon et al. (57) compared effects of weight loss or metoprolol treatment on left ventricular mass and blood pressure. An average weight loss of 8.3 kg resulted in a reduction in left ventricular mass/body surface area of 16%, and independent effects of weight loss and blood pressure reduction were observed.

In contrast to patients with moderate obesity, extremely obese patients who lost substantial weight following bariatric surgery showed more consistent decreases in left ventricular mass and left ventricular filling, as well as improved systolic and diastolic function (21,61–65). Improvements in structural and hemodynamic parameters appear to correlate with factors at baseline such as duration (65) and degree of obesity (62), degree of impaired loading (21), left ventricular mass (62), and degree of systolic dysfunction (63); following surgery, improvements have been correlated with percent of excess weight loss (62). Thus, improvements would be expected in those who are most obese, have the greatest baseline impairment and hypertrophy, and who lose more weight.

#### IV ELECTROCARDIOGRAM, ARRHYTHMIAS, AND SUDDEN DEATH

##### A Effects on the Electrocardiogram

Considering that obesity is associated with hemodynamic and structural changes of the heart, as well as with increased risk for sudden death, electrocardiographic (ECG) changes would not be unanticipated. Frank et al. (66) examined ECG findings in 1029 obese subjects, which were then correlated with degree of obesity, age, gender, and blood pressure. As obesity increased, there was increased leftward QRS axis, increased QRS voltage, and low QRS voltage was found in 4%. The QT interval corrected for heart rate (QTc) was abnormally prolonged in 28% and QTc prolongation correlated with degree of obesity. In trials where the ECG in obese subjects has been compared to lean controls, obese patients have had more leftward QRS axis (although pathologic left axis deviation was rare), lower QRS voltage, and more frequent T-wave flattening in the inferior and lateral leads (66–68). Alpert (67) contrasted the ECGs of 100 obese subjects (BMI  $48 \pm 2$  kg/m<sup>2</sup>) with 100 lean controls and found that 11/100 obese patients had low QRS voltage. None of these 11 subjects had elevated left ventricular mass/height index, although in the entire population, left ventricular mass index was elevated in 64/100. Alpert has proposed

that low QRS voltage results from electrical insulation by subcutaneous or epicardial fat, and furthermore, that the relatively low prevalence of low voltage may reflect a balance between obesity-related left ventricular hypertrophy and electrical insulation by fat. This is consistent with the limited ability of the ECG to detect left ventricular hypertrophy in obese patients, as estimates of sensitivity range from 18–76% (69,70); the wide variation also reflects differing methods of indexing LV mass and criteria for hypertrophy.

Prolongation of the QT interval has been an inconsistent finding in healthy obese subjects, and among trials the prevalence of prolonged QTc has ranged from 0% to 47% (66,67,71–73). Despite inconsistencies between investigations in frank QTc prolongation, Frank et al. (66), and more recently el-Gamal et al. (71) and Carella et al. (73) observed that QTc increased directly in proportion to degree of obesity or body fat. Factors that possibly explain the variability in QT findings include inclusion of subjects who were dieting or who had subclinical electrolyte abnormalities, or failure to control for timing of meal consumption in relation to testing (since food consumption transiently prolongs the QT interval) (74).

Disturbances in heart rhythm in lean and obese subjects were assessed on standard 12-lead ECG by Alpert (67), who found no significant differences between groups in sinus bradycardia or tachycardia. Frank (66) observed bradycardia (<60 bpm) in 19% of obese subjects, in contrast to tachycardia (>100 bpm) in 0.5%. To assess the relationship between obesity and ventricular ectopy, several trials have employed longer-term ECG or Holter monitoring. In lean and obese (with and without eccentric left ventricular hypertrophy) hypertensive patients who underwent 24-hr Holter monitoring and echocardiograms, Messerli et al. (75) found that ventricular ectopy occurred 10 times more frequently in the obese and 30 times more frequently in the obese with left ventricular hypertrophy. Both left ventricular mass and diastolic diameter correlated with complexity of ectopy, and the three subjects who experienced arrhythmia had the greatest left ventricular mass and diastolic diameter. In patients without known heart disease awaiting bariatric surgery, a nonsignificant increase in ectopy was observed during 24-hr holter monitoring in comparison to lean subjects (76). In a small number of moderately obese patients referred for suspicion of arrhythmia, frequency of ventricular ectopy correlated with BMI as well as with left ventricular mass index, but in a multivariate model including age and hyperinsulinemia, both BMI and left ventricular mass became nonsignificant (77).

## B Arrhythmia

Obesity promotes several risk factors for arrhythmia, including left ventricular hypertrophy, CHD, autonomic imbalance, and sleep apnea. While these factors may contribute to arrhythmia risk, documentation of malignant arrhythmias in obese patients with these risk factors has been scarce (75,77,78). Proposed mechanisms linking structural changes to arrhythmia include altered myocyte electrophysiology, fatty infiltration of the myocardium, myocardial fibrosis, myocardial ischemia resulting from diminished perfusion from dilatation and hypertrophy in combination with increased myocardial demand or work, and physical disruption of the conducting system by myocardial hypertrophy or fatty infiltration (78,79). Ventricular ectopy on 24-hr monitoring in obese patients has also been observed in association with hyperinsulinemia and with erythrocyte magnesium content in nondieting patients, possibly indicating defects in transmembrane cation exchange or abnormal intracellular concentration (77).

Abnormal heart rate variability, an index of autonomic balance reflecting sympathetic and parasympathetic contributions, is associated with risk for arrhythmia, congestive heart failure, and CHD (80,81). Reduced heart rate variability has been observed in obesity due to withdrawal of vagal activity and sympathetic predominance (76,81–84). Of interest, weight loss in the range of 9–32 kg has resulted in normalization of parasympathetic activity and heart rate variability (76,83–85). Whether weight loss-induced normalization of autonomic balance is associated with reduced cardiovascular morbidity, however, remains to be demonstrated.

Obstructive sleep apnea, a condition largely attributable to obesity, is associated with multiple rhythm disturbances including bradycardia (bradycardia followed by tachycardia), bradycardia, premature supraventricular and ventricular depolarizations, supraventricular tachycardia, and ventricular tachycardia (86). In 239 patients with obstructive sleep apnea, bradycardia was positively associated with BMI and severity of sleep apnea, but was observed in only 7% (87). Valencia-Flores et al. (88) conducted polysomnography in 52 consecutive patients with an average BMI of  $\sim 50 \text{ kg/m}^2$  who presented for outpatient obesity treatment. In this study, 98% had evidence of sleep-disordered breathing and 33% had severe sleep apnea. Cardiac rhythm disturbances were observed in 41% with severe apnea and in 27% of those with less severe sleep apnea. The type of rhythm disturbances noted included sinus arrhythmia (16%), premature ventricular complexes (16%), premature atrial complexes

(10%), ventricular tachycardia (6%), and supraventricular tachycardia (4%). In addition, changes suggestive of cardiac ischemia during sleep occurred in 10% of subjects.

## C Sudden Death

The first observation of increased risk of sudden death in obesity is attributed to Hippocrates, who over two millennia ago noted, “Sudden death is more common in those who are naturally fat than in the lean” (89). In the Framingham Heart Study, degree of overweight was highly predictive of sudden death in men (the small number of deaths observed in women precluded significance), and risk for sudden death was independent of traditional CHD risk factors (40). In the same population, a fivefold increased risk of sudden death was observed in those with congestive heart failure as compared to the general population; although the degree of obesity in those with congestive failure was unreported, there is a plausible link among obesity, congestive heart failure, and sudden death (90). In a retrospective survey by U.S. bariatric surgeons, a total of 60 sudden deaths were noted (91). In these patients, eight died awaiting gastric surgery for obesity, 14 died within 10 days following surgery, and the remainder died 12 days to 4 years after surgery. In those patients with available ECGs, 29/38 demonstrated prolonged QTc, indicating increased risk for arrhythmia. Despite the apparent increased risk for sudden death, there has been difficulty in documenting death due to malignant arrhythmia (a final lethal event in  $\sim 50\%$  of patients dying of cardiovascular disease) (92).

Autopsy results from obese sudden-death patients suggest that ventricular hypertrophy or dilated cardiomyopathy is the most common finding, whereas other causes to which death could be attributed were variable. In seven young (6–32 years old) obese persons with sudden death, Bharati and Lev (79) found ventricular hypertrophy in 6/7 and greater-than-expected rates of fatty and fibrotic infiltration of the cardiac conduction system. In a study of 22 older (mean age 35 years) sudden death patients with a mean BMI of  $57 \text{ kg/m}^2$ , dilated cardiomyopathy was found in 10, hypertrophy without dilatation in four, coronary atherosclerosis in six, and pulmonary embolus in one.

In the late 1970s, 58 cases of death were reported in patients consuming very low calorie diets (93–97). Analysis of a subset of 17 of these patients revealed that death occurred during dieting in 10/17, while the remainder died during refeeding (96). Based on available ECGs, 75% had either prolonged QTc or low QRS voltage, or

both. In all 11 patients who died under monitored conditions, ventricular arrhythmias were observed. Fislér (98) compiled trials reporting sudden death or ECG abnormalities in obese dieting patients prior to 1992, and several subsequent reports have now been published (72,99–102). It appears that starvation lasting more than several weeks, very low calorie diets with poor-quality protein, and surgical weight loss without nutritional monitoring were associated with QTc prolongation, low QRS voltage, and sporadic arrhythmias (93–98,103). In contrast, very low calorie diets containing sufficient quantities of good quality protein and supplemented with micronutrients (72,98–101,104–107), and starvation of brief (10 days) duration (102) have not been associated with abnormalities of cardiac conduction, voltage, or rhythm.

Sudden death is now rarely reported in patients undergoing surgical weight loss, suggesting that diet quality, preoperative assessment, and postoperative monitoring have improved. While no definitive underlying mechanism was found for sudden death during prolonged starvation or very low calorie diets, a number of factors have been proposed. Dietary factors include consumption of inadequate or poor-quality protein, electrolyte deficiencies, and copper deficiency (possibly secondary to use of collagen, a protein source low in copper) (93,98,108–110). Other proposed factors include myocardial protein depletion and increased sensitivity to the sympathetic stimulation associated with refeeding (93,98). Another proposed factor contributing to sudden death is that there is a critical threshold for loss of body weight or fat free mass. In a reanalysis in the original 58 patients, Van Itallie and Yang (93) found a direct relationship between initial BMI and months of survival on a very low calorie diet. The authors suggest that initially high levels of fat-free mass and fat might confer a survival advantage by delaying loss to a critical level of fat-free mass or myocardium.

## **V ATHEROEMBOLIC DISEASE: CORONARY HEART DISEASE AND STROKE**

### **A Coronary Heart Disease**

Obesity is associated with increased risk for CHD, reflecting increased risk for both atherosclerosis of the coronary arteries and ischemic events. Accordingly, the American Heart Association recently classified obesity as a major risk factor for CHD independent of traditional CHD risk factors (111). The development of atherosclerotic disease represents a progression from

plaque formation to plaque rupture and thrombus formation, and finally to fibrosis (112). Obesity and central body fat distribution have been demonstrated to promote processes contributing to each of these stages (Table 2). Traditional CHD risk factors, such as diabetes, hypertension, and dyslipidemia, are discussed elsewhere in this volume. Several emerging nontraditional risk factors for CHD are associated with obesity, including the role of chronic inflammation, endothelial dysfunction, and alterations in hemostasis and coagulation.

Coronary heart disease has recently been associated with a state of chronic low-level inflammation, a state that may indicate underlying CHD, but also may contribute to pathogenesis (113–115). Several circulating markers of inflammation, such as C-reactive protein (CRP) and fibrinogen, have been identified as predictors of CHD incidence and prognosis. CRP is an acute phase protein that is elevated in response to inflammation or infection. CRP has been found to correlate directly with degree of overweight, body fat, and central fat distribution; in addition, CRP has been associated with insulin resistance, activation of coagulation, and subclinical atherosclerosis (113,114,116–121). In several trials, CRP was a significant predictor of new CHD events and prognosis after CHD events, and use of CRP has improved prediction of CHD events when combined with blood lipids (119,122,123). CRP is produced in the liver primarily under the control of interleukin-6 (IL-6), a pro-inflammatory cytokine produced in macrophages, lymphocytes, and fat cells (124). IL-6 itself has been associated with CHD (125), and also increases hepatic

**Table 2** Risk Factors for CHD Associated with Obesity

|   |
|---|
| Metabolic                               |
| Diabetes                                |
| Insulin resistance and hyperinsulinemia |
| Dyslipidemia                            |
| Androgen excess                         |
| Cardiovascular                          |
| Hypertension                            |
| Left ventricular hypertrophy            |
| Endothelial dysfunction                 |
| Hematologic                             |
| Hyperviscosity                          |
| Pro-coagulant state                     |
| Impaired fibrinolysis                   |
| Chronic inflammation                    |
| Hyperuricemia                           |
| Obstructive sleep apnea                 |

---

production of fibrinogen, induces insulin resistance, stimulates lipolysis, increases endothelial release of adhesion molecules, and increases platelet aggregation (124). Yudkin (124) has proposed a central role for IL-6 in the link between obesity and CHD, since IL-6 production and circulating levels increase in proportion to body fat. Accordingly, increased levels of circulating IL-6 may stimulate a pro-thrombotic state and endothelial dysfunction, while CRP serves as marker of inflammation. However, this model remains speculative, and the exact mechanisms relating inflammation and pro-inflammatory cytokines to obesity and CHD require further elucidation.

Obesity also appears to induce a state of hemostatic imbalance favoring coagulation. Positive relationships have been observed between BMI or body fat and fibrinogen, Von Willebrand factor, factor VII, factor VIII, and plasminogen activator inhibitor 1 (PAI-1), the primary inhibitor of fibrinolysis (126–129). In prospective epidemiologic trials, fibrinogen, Von Willebrand factor, factor VII, and PAI-1 levels have been associated with incident CHD, CHD events, or long-term survival in those with stable CHD (34,126,128,130,131).

Impaired endothelial vasodilatory responses have been proposed to increase risk for CHD, either acutely due to ischemia, or as markers of early dysregulation (vasodilatory, thrombogenic, and mitogenic functions) predisposing to CHD (132). In obese patients, endothelial nitric oxide-dependent responses to insulin, ischemia, or acetylcholine have been abnormal in peripheral (133–137) and coronary (138) arteries, while vasodilation not dependent on endothelial nitric oxide appears largely unaffected. Abnormal nitric oxide-dependent endothelial relaxation has been observed in obese subjects in relation to degree of obesity and central fat distribution, which has been independent of traditional risk factors.

Many, but not all, epidemiologic studies have shown significant relationships between excess body weight and CHD incidence, events, or mortality (139–160). Increased risk of CHD mortality was also observed in those who were obese as adolescents, regardless of adult weight (161), and in those who gain weight in adulthood (156). The lack of consistent relationship between obesity and CHD has been attributed to a number of methodologic issues, which include misclassification bias introduced by use of anthropometric surrogates of body fat, failure to control for smoking status and body fat distribution, and use of inappropriate control populations (151,162). The most consistent relationship observed between obesity and coronary artery disease is a univariate one, without control for other CHD risk fac-

tors (163). In the Framingham Heart Study (40,164), the 26-year incidence of CHD increased proportionately to excess weight. In that population, obesity was associated with increased CHD incidence of 2.4-fold in women and twofold in men under the age of 50 years. In a prospective study of BMI and mortality, Calle et al. (165) found that CHD mortality risk in women significantly increased when BMI exceeded 25 kg/m<sup>2</sup>, and an approximately twofold risk of CHD mortality was observed in women with BMI > 35 kg/m<sup>2</sup>. In men, CHD mortality risk increased significantly at BMI > 26.5 kg/m<sup>2</sup>, and risk of mortality was 2.9-fold with a BMI of 35 kg/m<sup>2</sup> (165).

A consistent relationship between CHD and body fat distribution has been observed, and increased abdominal adiposity appears to increase CHD at all levels of body weight (140,152,160,166–168). In some populations, central adiposity has been more predictive of events or mortality than degree of overweight (128, 140,152,156,158,168,169).

In multivariate models that included traditional CHD risk factors in addition to obesity, independent effects of obesity on CHD have been observed with less consistency. However, several studies have demonstrated a persistent, but diminished, contribution of body weight to CHD and myocardial infarction risk when factors such as blood pressure, blood lipids, diabetes, smoking, and age were included in multivariate models (40,139,142,156,170,171). In the Nurses' Health Study, the magnitude of elevated relative risk of coronary disease between highest and lowest BMI quintiles was diminished, but not eliminated, by adjustment for several known risk factors (RR 3.4 vs. 1.9, unadjusted vs. adjusted for other risk factors) (156).

Associations between body weight and coronary artery disease among nonwhite groups have been observed less frequently than in primarily white populations. An inconsistent relationship has been found for blacks (141,160,172,173), although two recent trials have found that obesity confers risk of CHD similar to white controls (158) or white populations. Hispanics have a disproportionate amount of obesity, central obesity, diabetes, and hypertension in comparison to non-Hispanic whites, yet in middle-aged and older Hispanics, mortality from cardiovascular disease has been less than or equal to that in non-Hispanic whites (146,174). In the Strong Heart Study (147,175), three geographically diverse subgroups of American Indians were assessed for rates of coronary heart disease and associated risk factors, revealing that obesity was a significant predictor of coronary heart disease independent of other traditional risk factors, although the

overall occurrence of coronary heart disease was less than that reported in other populations.

While obesity may promote risk for CHD, diagnosis is complicated by limitations due to weight or body habitus. Accuracy of myocardial perfusion imaging may be significantly reduced when BMI exceeds 30 kg/m<sup>2</sup> (176). Many exercise treadmills and angiographic tables cannot accommodate weights over 300 lb. Thus, in extreme obesity, greater reliance must be placed upon clinical factors and the electrocardiogram. In addition to difficulties in diagnosis, treatment of CHD may also be adversely influenced by obesity. In obese patients undergoing coronary artery bypass grafting, there have been increased rates of sternal wound infection (177), saphenous vein site infection (178), postoperative respiratory complications (179,180), prolonged hospital stay (181), and readmission after discharge (182).

## **B Stroke and Peripheral Vascular Disease**

Obesity and central body fat distribution increase the risk for ischemic stroke and accelerated atherosclerotic disease of the carotid artery, but do not appear to increase the risk for hemorrhagic stroke (166,167,183–188). Effects of obesity on stroke or carotid atherosclerotic disease independent of traditional risk factors have been only inconsistently reported (166,186,189–192). In regard to peripheral vascular disease, a small number of investigators have assessed the role of obesity and have found little contribution of obesity to clinical disease (193–195). Further, noninvasive measures of carotid and femoral intima-media thickness (a measure of pre-clinical atherosclerosis) suggest that excess body fat is associated with thickening of only the carotid arteries (196–198).

## **C Effects of Weight Loss on CHD and Atherosclerosis**

Weight loss in overweight, moderately obese, and extremely obese subjects has been demonstrated to improve CHD risk factors such as blood pressure (49,186,199,200), blood glucose and insulin concentrations (201,202), and blood lipids (186,199,203). Hemostatic imbalance appears to be normalized by weight loss, as subjects who lost 8–14 kg demonstrated marked decreases in PAI-1, factor VIIc, and fibrinogen (186,203,204). However, those who regain weight again revert toward a pro-thrombotic state. Vasodilatory function response to ischemia-induced forearm blood flow, an indicator of endothelial vasodilatory function, was significantly improved with weight losses of 5–7 kg (134).

CRP was also reduced by 26% in association with an average weight loss of 8 kg in moderately obese women (205). The effects of weight loss on early atherosclerosis were assessed in two trials by pre- and post-weight loss measurement of carotid intima-media thickness. In one trial, intima-media thickness was reduced, which was independent of changes in LDL cholesterol and PAI-1 (186). In the second trial, the progression rate of intima-media thickness was slowed to that of lean controls (188).

The promising effects of weight loss on risk factors and subclinical atherosclerosis have not previously been reflected in observational trials relating CHD morbidity and mortality with weight loss, in part due to lack of differentiation between voluntary and involuntary weight loss as well as the small numbers of those who maintain lost weight over years (206). However, more recent trials limited to those reporting volitional weight loss have been more encouraging (207,208). In 4970 overweight diabetic patients, intentional weight loss over a 12-year period was associated with a 28% reduction in cardiovascular mortality (208). However, further prospective trials specifically designed to address this issue are needed to confirm effects on mortality (209).

## **VI CARDIOVASCULAR EFFECTS OF APPETITE SUPPRESSANTS**

In July 1997, 24 cases of valvular heart disease were reported in patients taking dl-fenfluramine or dexfenfluramine, prompting the U.S. Food and Drug Administration (FDA) to issue a public health advisory. A month later descriptions of these cases, as well as an additional 29 cases, were published (210–212). Regurgitation was observed in both left- and right-sided valves, but mitral and aortic valves were more frequently involved. On gross examination and on echocardiogram, affected valves were described as having a glistening appearance on echocardiogram (210). Initial histopathology revealed changes identical to those in valvulopathy associated with carcinoid syndrome or with ergotamine use (210). Five preliminary surveys in patients taking fenfluramine alone, or in combination with phentermine, suggested that valvulopathy occurred in 33% (213), leading to withdrawal of dl-fenfluramine and dexfenfluramine from the U.S. market in September 1997. These early surveys were criticized, however, for failure to employ FDA criteria for valvular disease and because they were uncontrolled. Subsequent surveys have generally used FDA criteria, and reflect a variety

of methodologies. In contrast to initial estimates of valvulopathy in 33% of fenfluramine users, subsequent trials have reported a lower prevalence of valvulopathy, with estimates of fenfluramine-related valvulopathy of 0% (214,215), 4.3% (216), 6.9% (217), 7.6% (218), 8% (219), 8.8% (220), 16% (221), 16.5% (222), 23% (223), 26% (224), and 31% (225,226). Likelihood of valvulopathy was increased with duration of treatment (220–222,225–227), dosage (228), or when fenfluramine was taken in combination with phentermine (217,220,229). In patients with valvulopathy who have been reexamined by echocardiogram ~1 year after initial examination, there appears to be little evidence for progression of valvular dysfunction, and trends toward resolution have been observed (224,230,231). Mast et al. (231) found improvement in 17/38 patients with baseline valvulopathy, while no change was noted in 19/38 and worsening occurred in two. In another study of five patients with valvulopathy, improvement was noted in 5/5 patients with resolution in 3/5 (224).

Valvular heart disease has not been observed to occur more frequently owing to obesity itself (61,232). There also has been no valve disease associated with sibutramine, a serotonin and norepinephrine reuptake inhibitor antiobesity medication (233). Use of the serotonergic reuptake inhibitor fluoxetine in combination with phentermine has not been associated with valvulopathy in one study (234), but confirmatory trials are needed.

Use of certain over-the-counter or herbal weight loss aids has also been associated with cardiovascular morbidity and mortality. Increased risk for hemorrhagic stroke in women has been associated with use of the over-the-counter weight loss drug phenylpropanolamine, leading to its withdrawal from the U.S. market (235). Use of ephedra, an herbal preparation containing variable amounts of ephedrine alkaloids, has been associated with a number of cardiovascular side effects, including hypertension, tachycardia, myocardial infarction, and stroke (236). Further, chronic use of sympathomimetics such as ephedra may increase risk for hemodynamic instability during anesthesia secondary to catecholamine depletion (237).

## VII CONCLUSION

Obesity is associated with substantial risk for cardiovascular morbidity and mortality. The obese state is characterized by hemodynamic and structural adaptation, and promotes cardiovascular disease through traditional, newly described, or as yet undefined risk

factors. The salutary effects of weight loss on risk factors and cardiovascular disease itself provides encouragement that weight losses that are currently achievable will have longer-term benefit. Emerging factors linking obesity and CHD, such as chronic inflammation, not only help elucidate pathogenesis, but provide specific targets for intervention.

### I DYSLIPIDEMIC PHENOTYPES IN CORONARY HEART DISEASE: BEYOND CHOLESTEROL

The measurement of plasma lipid levels is now commonly used to assess the risk of coronary heart disease (CHD). Several epidemiological studies have shown that there is a significant positive relationship between blood cholesterol levels and deaths associated with CHD (1–3). In the Multiple Risk Factor Intervention Trial (MRFIT), Stamler et al. (4) showed that in a sample of 356,222 male subjects, increased blood cholesterol levels were associated with a progressive increase in CHD mortality. However, despite the fact that numerous studies have shown this relationship, Genest et al. (5) have reported that nearly 50% of patients having ischemic heart disease (IHD) have plasma cholesterol levels equal to or even lower than those of healthy subjects.

Accordingly, Sniderman and Silberberg (6) emphasized that although the mean blood cholesterol concentration in CHD patients is generally significantly higher than that of healthy subjects, there is a considerable overlap between CHD patients and healthy subjects. Thus, the clinical value of total cholesterol measurement alone is of limited use in distinguishing CHD pa-

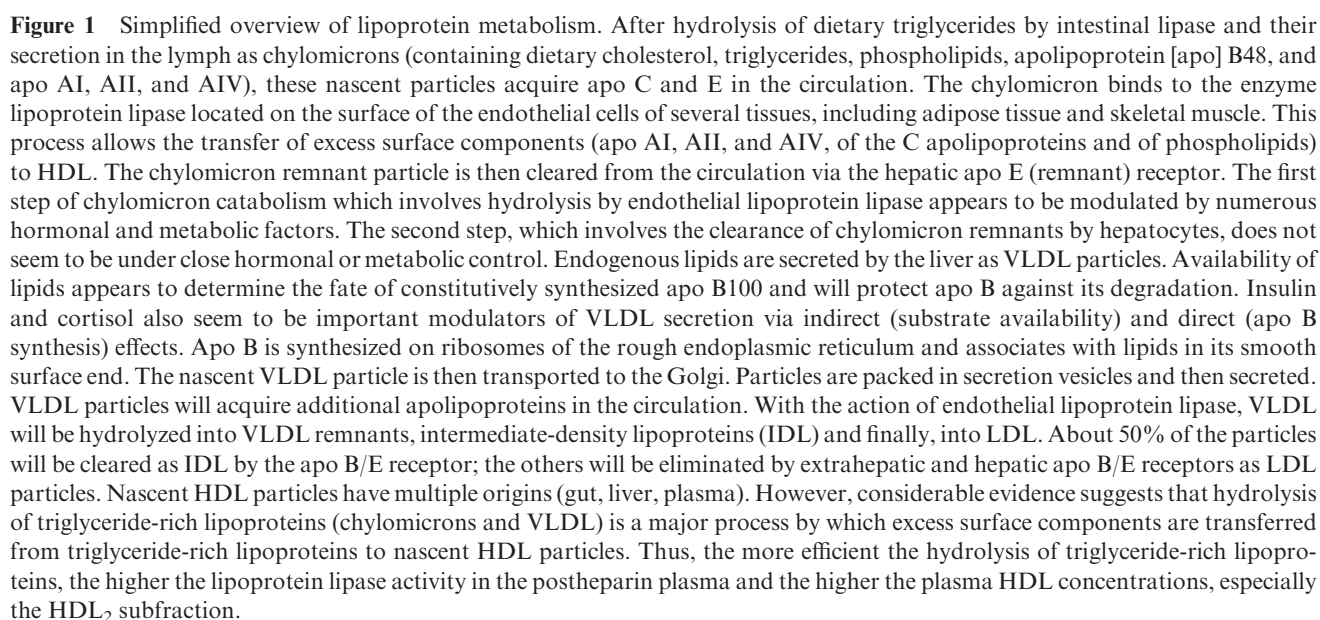

tients from healthy subjects. It was therefore suggested that additional determinations of blood lipid variables were needed to more accurately assess risk.

Plasma cholesterol is a hydrophobic compound and is transported in the blood by lipoproteins. Lipoproteins vary in size, composition, and density, and four main families can be identified: chylomicrons, very low-density lipoproteins (VLDL), low-density lipoproteins (LDL), and high-density lipoproteins (HDL) (Fig. 1). Chylomicrons are large particles found after a meal which are responsible for the transport of alimentary lipids. They are generally absent from the fasting plasma of healthy subjects. Triglyceride (TG) and cholesterol molecules of hepatic origin are secreted in VLDL particles which are converted to LDL following hydrolysis by the enzyme lipoprotein lipase (LPL). During the hydrolysis of chylomicrons and VLDL, excess surface component aggregates to form nascent HDL particles. Additional newly formed and immature HDL particles originate from the intestine and the liver.

#### A LDL Cholesterol: A Major Culprit in CHD

Numerous prospective studies that have measured cholesterol in the lipoprotein fractions (VLDL, LDL, and HDL) have reported highly significant associations

between plasma LDL cholesterol levels and the risk of CHD (4,7–10). Furthermore, with the development of HMG-CoA reductase inhibitors (statins), clinicians now have access to powerful tools to significantly lower LDL cholesterol concentrations with associated clinical benefits. Primary and secondary prevention trials have shown that LDL cholesterol lowering can reduce the risk of a first or recurrent CHD event by ~30% (11–16). Thus, the development of statins has been a remarkable breakthrough allowing clinicians to better manage CHD risk. However, these findings are of little help for the remaining 70% of statin-treated patients who remained at risk for CHD despite being treated with a LDL cholesterol-lowering drug. Furthermore, as for total cholesterol, prospective and cross-sectional studies have shown that there is a considerable overlap in the distribution of LDL cholesterol levels between CHD patients and asymptomatic individuals (5,17,18). Thus, other variables (established risk factors and other metabolic markers of CHD risk) need to be considered to refine our assessment of CHD risk.

Among those additional risk factors, several prospective studies have shown that when low HDL cholesterol is reduced, there is an increased risk of CHD and of related mortality (17,19–21). In both men and women, plasma HDL cholesterol has been inversely related to the incidence of CHD, and this relationship has been reported to be largely independent of other parameters of the lipid profile (22). These data support the notion that low HDL cholesterol levels increase CHD risk. It thus seems reasonable to assume that an intervention resulting in an increase in HDL cholesterol levels could decrease the incidence of IHD.

This hypothesis was recently tested in the Veterans Affairs High-Density Lipoprotein Intervention Trial (VA-HIT), which examined the effect of a HDL cholesterol-raising therapy using a fibrate (gemfibrozil) in a sample of middle-aged men with documented CHD who were recruited on the basis of their low HDL cholesterol levels (23). Over 5 years, fibrate therapy reduced the risk of a recurrent CHD event by 22% in the absence of any LDL cholesterol-lowering effect of gemfibrozil (23). These results confirmed that HDL cholesterol raising with fibrate therapy was relevant for the secondary prevention of CHD in patients with low HDL cholesterol levels. These results are also consistent with results from transgenic animal models which have shown that the overexpression of genes modulating HDL levels (A1, AII, etc.) resulted in a slower progression of atherosclerosis (24).

In this regard, it is also important to emphasize that patients who have low HDL cholesterol levels also fre-

quently have elevated TG concentrations. Results of some, but not all, prospective epidemiological studies have indicated that an elevated TG concentration did not constitute an independent risk factor for CHD when statistical corrections were made for other lipoprotein or lipid variables such as HDL cholesterol (25). However, results of the PROCAM (Prospective Cardiovascular Munster) study (8), the Helsinki Heart Study (26), and the Copenhagen Male Study (27) have all shown that the presence of low HDL cholesterol levels accompanied by hypertriglyceridemia was predictive of the highest risk of CHD. Consequently, a low plasma HDL cholesterol concentration must be given special attention by the clinician, particularly when it is accompanied by elevated TG levels.

Mechanisms have been proposed in order to explain the protective effect of HDL in CHD. HDL cholesterol has been suggested to be involved in the reverse cholesterol transport, a concept introduced by Glomset (28) in the late 1960s and considerably expanded upon since the identification of the ABC-1 (adenosine triphosphate-binding cassette transporter-1) and of the SR-B1/CLA receptors (Fig. 2), which have allowed a better understanding of how free cholesterol may leave cells such as macrophages through the ABC-1 receptor, be transported by HDL, and be transferred back to the liver through the interaction of HDL with a docking receptor SR-B1/CLA-1 (29,30). There is also evidence that HDL particles can have anti-inflammatory and antioxidative properties that may contribute to atherosclerosis protection (31).

Another model suggests that the presence of high plasma HDL cholesterol levels could be indicative of effective catabolism of TG-rich lipoproteins. As shown in Figure 3, the rapid breakdown of chylomicrons and VLDL by the action of the enzyme LPL could lead to an increase in the production of HDL, more specifically, the HDL<sub>2</sub> subfraction, which seems to be particularly abundant when LPL activity is high. Consequently, the role of LPL in the breakdown of TG-rich lipoproteins and the production of HDL could contribute to explain the well-established inverse relationship existing between plasma TG and HDL cholesterol concentrations.

Moreover, lipid transfer proteins found in plasma allow the exchange of lipids between different lipoprotein fractions. In fact, one of these transfer proteins, cholesteryl ester transfer protein (CETP), favors the exchange of the TGs found in TG-rich lipoproteins for HDL cholesteryl esters, resulting in the depletion of cholesterol in HDL particles. In addition, and as mentioned previously, a low LPL activity contributes

**Figure 2** The role of adenosine triphosphate-binding cassette transporter (ABC-1) and of CLA-1 docking protein in cellular cholesterol efflux and of the scavenger receptor class B type 1 (SR-B1) in reverse cholesterol transport. Free cholesterol (C) may be eliminated from cells such as macrophages through a process mediated by the ABC-1 receptor. After esterification of this free cholesterol by the enzyme lecithin-cholesterol acyl transferase (LCAT), this esterified cholesterol (CE) contained in maturing HDL particles will be transported back to the liver and selectively taken up by hepatocytes through the interaction with a docking receptor SR-B1/CLA-1. Apo: apolipoprotein; CETP: cholesteryl ester transfer protein.

to a decreased production of HDL precursors originating from the aggregation of an excessive number of surface components released by the hydrolysis of VLDL and chylomicrons. In this regard, we further examined the metabolic heterogeneity underlying low HDL cholesterol levels (32). We found that individuals with low HDL cholesterol but normal TG levels did not show elevated plasma insulin levels either in the fasting state or in response to an oral glucose challenge. We also found that isolated hypertriglyceridemia was not associated with increased plasma insulin levels. However, the combination of low HDL cholesterol and of moderately elevated TG concentrations was associated with a considerable and significant increase in plasma insulin concentrations measured in the fasting state and in response to the oral glucose load, suggesting that this specific dyslipidemic state was particularly related to hyperinsulinemia stemming from resistance of tissues to insulin.

In the PROCAM Study conducted in Munster, Germany (27), and in the Helsinki Heart Study (26) the combination of high TG and low HDL cholesterol levels was associated with a significant increase in the risk of CHD and a high percentage of coronary events were specifically related to this dyslipidemia. For instance,

among individuals of the PROCAM study whose TG and HDL cholesterol levels were  $>200$  mg/dL and  $<35$  mg/dL, respectively, the incidence of coronary events observed over a 6-year period was 5.3-fold higher (128 cases/1000 people) than among subjects with a normal lipid profile (24 cases/1000 people) (27). Consequently, this dyslipidemic profile (including hypertriglyceridemia and hypoalphalipoproteinemia) associated with hyperinsulinemia secondary to insulin resistance significantly increases the risk of CHD among individuals with this cluster of metabolic abnormalities.

Dr. Gerald Reaven (33) was the first to suggest the term “insulin resistance syndrome” to describe a cluster of metabolic abnormalities that includes hypoalphalipoproteinemia, hypertriglyceridemia, hyperinsulinemia, and increased blood pressure. To measure the sensitivity to insulin, Dr. Reaven used the euglycemic-hyperinsulinemic clamp in about 100 normal subjects as well as in glucose intolerant and type 2 diabetic patients (33). In this technique, a certain amount of insulin is

### 1. Increased lipid exchange due to CETP

### 2. Low LPL activity

**Figure 3** (1) Lipid transfer proteins contribute to the exchange of lipids between the various lipoproteins. In this case, cholesteryl ester transfer protein (CETP) allows the exchange of triglyceride (TG) from TG-rich lipoproteins for cholesteryl esters of the HDL fractions, which ultimately leads to a reduced cholesterol content of HDL particles. (2) A low lipoprotein lipase (LPL) activity contributes to a reduced production of nascent HDL particles originating from excess surface components following the hydrolysis of VLDL particles.

infused in order to induce hyperinsulinemia to a predetermined level. Obviously, the rate at which blood sugar levels drop varies if there is no simultaneous infusion of glucose. The greater the sensitivity to insulin, the faster the blood glucose levels fall, and the higher the quantity of glucose needed to maintain euglycemia. Consequently, the sensitivity to insulin, or the M value, corresponds to the amount of glucose required to maintain a normal blood glucose level under a standardized hyperinsulinemic state and this value is expressed in milligrams of glucose infused per kilogram body weight per minute.

Reaven and colleagues (33) next subdivided the group of 100 nondiabetic subjects according to fasting insulin concentrations. The first quartile comprised individuals with the highest blood insulin levels; the fourth, individuals with the lowest. Within these four groups, considerable differences were observed in terms of *in vivo* sensitivity to insulin. Subjects of the lowest insulin quartile were very sensitive to insulin (M value >300), whereas subjects of the highest insulin quartile were clearly insulin resistant (M value barely above 100). Two critically important observations were made. Firstly, considerable differences in terms of sensitivity to insulin were found even among individuals with normal glucose tolerance. Furthermore, in 25% of normal individuals, the magnitude of the insulin resistant state was similar to that found among glucose-intolerant individuals or type 2 diabetic patients. Consequently, Reaven concluded that insulin resistance is prevalent in our population since 25% of nondiabetic subjects seem to have this characteristic.

There is considerable evidence indicating that insulin resistance is associated with a pro-atherogenic dyslipidemic state (34,35). Considering the recently confirmed high prevalence of insulin resistance for which the cluster of metabolic abnormalities has been defined as the “metabolic syndrome” in the recent National Cholesterol Education Program Adult Treatment Panel III (NCEP-ATP III) guidelines (36), this condition is likely to represent the most common cause of dyslipidemic states found in CHD patients (37,38).

#### **B “Normal” LDL Cholesterol Levels in Patients with Metabolic Syndrome: Potentially Misleading Information?**

Plasma LDL cholesterol levels are frequently within the normal range in patients with high TG and low HDL cholesterol concentrations and showing the features of the metabolic syndrome (17,33). However, other techniques have made it possible to conclude that this form

of dyslipidemia related to insulin resistance is frequently associated with high levels of apo B (the apolipoprotein of LDL) in the presence of a relatively normal LDL cholesterol value, suggesting the presence of a greater number of LDL particles relatively depleted in cholesteryl esters. Additional analytical techniques that have used gradient gel electrophoresis to separate LDL on the basis of size have helped confirm the fact that the high TG/low HDL cholesterol dyslipidemia is associated with an increased proportion of small, dense LDL particles (39–41).

In this regard, Austin et al. (41) suggested that more than 80% of individuals characterized by a low proportion of dense LDL (phenotype A), have TG levels <92 mg/dL (1.05 mM). Consequently, it could be possible, on the basis of fasting TG concentrations, to identify a fairly large percentage of individuals with an increased proportion of dense LDL particles (phenotype B). Furthermore, >50% of patients with elevated apo B levels could also be characterized by an atherogenic phenotype that would include hypertriglyceridemia, hypoalphalipoproteinemia, and an increased proportion of smaller and denser LDL particles (41). It is appropriate to emphasize that this atherogenic phenotype is frequently observed in CHD patients with nearly normal plasma cholesterol or LDL cholesterol concentrations (37,41).

From a clinical perspective, it is interesting to note that the atherogenic B phenotype is found in ~20–30% of the population (25,41). This figure is similar to the estimated (33)/reported (42) prevalence of the insulin resistance syndrome (also now frequently referred to as the metabolic syndrome because of its definition in the recent NCEP-ATP III) (~25–30%) (33). Thus, the hypothesis has been put forward that a high proportion of patients characterized by hyperapobetalipoproteinemia and the atherogenic phenotype B may have a common metabolic disorder: insulin resistance.

The Québec Cardiovascular Study has published 5-year prospective data, which provided findings relevant to the present discussion (9). In this study, 2103 healthy men aged in their late 50s and initially free from clinical manifestations of IHD were followed for a period of 5 years for incidence of a first IHD event. Although plasma cholesterol concentrations were higher (7%) in men who developed IHD than in men who remained healthy, the most substantial differences were noted for the total cholesterol/HDL cholesterol ratio (16%) and apo B levels (12%) (9). We then used a simple algorithm to quantify the prevalence of dyslipidemic phenotypes in this population (9). While we found that type II dyslipidemia (hypercholesterolemia) was more prevalent

among IHD men than in healthy men, hyperapo B (with or without hypertriglyceridemia) was the most prevalent abnormality among men who developed IHD. Stepwise logistic regression analyses revealed that apo B concentration analysed as a continuous variable was the best lipoprotein component predictive of IHD (43).

However, in a model excluding apo B, the total cholesterol/HDL cholesterol ratio came out as the best variable of the lipoprotein profile to predict IHD risk (43). It is important to point out that both apo B and the total cholesterol/HDL cholesterol ratio are increased in an insulin resistant state, which provides further support that insulin resistance substantially increases the risk of IHD. In this regard, no prospective study has reported data on the risk of IHD associated with an impaired *in vivo* insulin action. A few prospective studies, however, have measured fasting plasma insulin concentrations as a crude index of insulin sensitivity. These studies reported that hyperinsulinemia was associated with an increased risk of IHD in men (44–47). As hyperinsulinemia resulting from *in vivo* insulin resistance is associated with a dyslipidemic state which includes hypertriglyceridemia, elevated apo B levels, and reduced HDL cholesterol concentrations, it was still unclear whether the hyperinsulinemia-IHD relation is independent from the concomitant alterations in plasma lipoprotein levels. Results from the Paris and Caerphilly prospective studies had suggested that the risk associated with hyperinsulinemia was no longer significant after control for plasma TG levels (47–49).

### **C Impact of the Features of the Insulin Resistance/Metabolic Syndrome on CHD Risk: Evidence from the Québec Cardiovascular Study**

The 5-year follow-up results of the Québec Cardiovascular Study provided data supporting the concept that the cluster of metabolic abnormalities which accompanies hyperinsulinemia (as a crude marker of insulin resistance) was predictive of a substantially increased risk of IHD (50). First, the 114 men who developed IHD during the 5-year follow-up period were matched for age, body mass index (BMI), smoking, and alcohol consumption with 114 men who remained healthy. We then excluded diabetic and IHD patients who could not be matched with controls because of extreme smoking habits, and we were able to match 91 nondiabetic cases and 105 controls (50). Fasting insulin concentrations were initially 18% higher in men who then developed IHD than in those who remained healthy. Furthermore,

logistic regression analyses revealed that insulin levels remained associated with IHD after adjustment for concomitant variation in plasma lipoproteins including apo B concentrations (50). Two other markers of the metabolic syndrome were found to be predictive of an increased IHD risk in the Québec Cardiovascular Study: apo B concentration and small LDL particles (51,52).

As the above features of the metabolic syndrome (hyperinsulinemia, elevated apo B, and small LDL particles) are simultaneously observed, we were also interested in quantifying the IHD risk associated with this triad of metabolic abnormalities (53). We found that the presence of this atherogenic metabolic triad was predictive of a 20-fold increase in the risk of IHD in middle-aged men of the Québec Cardiovascular Study (53). Thus, the clinician dealing with type 2 diabetic patients or with nondiabetic but insulin-resistant individuals should not only focus on plasma cholesterol or LDL cholesterol levels as the simultaneous presence of hyperinsulinemia, elevated apo B, and increased proportion of small LDL, which is clearly predictive of a substantially increased IHD risk. The prevalence of this cluster of metabolic abnormalities is such that it probably represents the main cause of CHD in our population. It should also be further emphasized that this insulin resistance/metabolic syndrome will frequently be found among subjects with “normal” cholesterol and LDL cholesterol levels (37).

## **II OBESITY, BODY FAT DISTRIBUTION, AND DYSLIPIDEMIAS**

Obesity is generally considered to be detrimental to cardiovascular health (3,54) and has long been associated with the presence of dyslipidemic states and CHD (54–56). Although some prospective studies have shown that obesity is a significant risk factor for CVD and related mortality in univariate analyses, it should be recognized that this association has generally been found to be rather weak, the relative risk ratio barely reaching 1.5 in overweight subjects in comparison with nonobese individuals (3,57–59). Multivariate analyses conducted in some studies failed to identify obesity as an independent risk factor for CVD (60,61). Thus, whether or not obesity *per se* is an independent predictor of CVD-related mortality has remained controversial, and this issue is still a matter of some debate in the scientific community.

In this regard, three possibilities have been raised to explain the weak association between obesity and mor-

tality (62). First, most epidemiological studies have used anthropometric correlates of total body fat, which only provide a crude assessment of total body fatness. In addition, in order to observe the detrimental effects of disturbances in carbohydrate and lipid metabolism on clinical manifestations of CVD, it is likely that a prolonged follow-up may be necessary. Prospective studies that have reported positive associations between relative weight and mortality had follow-up periods of 10–15 years and even more (63). Finally, and most importantly, there is a body of data indicating that the health hazards of obesity are more closely related to the localization of excess body fat rather than to an elevated body weight per se. For instance, although obesity is a highly prevalent condition among patients showing metabolic aberrations, the magnitude of the associations reported has been quite variable, and clinicians have often been confronted with the metabolic heterogeneity of obesity. Therefore, it is important to adequately define obesity as a health hazard in order to develop measures aimed at the prevention and treatment of its complications (64).

Body weight expressed as a function of height has been used for a long time to obtain a crude measurement of body fatness. More than a century ago, Quetelet (65) noted that body weight (kg) was proportional to height squared ( $m^2$ ). Later on, Keys and colleagues (66) redefined the Quetelet index as the BMI which also divides the body weight (kg) by height squared ( $m^2$ ). This measure is now commonly used as a valuable index of relative weight and obesity (67). Some studies that have used the BMI to evaluate body composition have reported significant associations with morbidity and mortality (54,58,63,68). Although very useful to estimate overall obesity, the BMI has limitations. Individuals who do not have a large excess of body fat such as those with large muscle masses would be misclassified as having a high-risk body weight. Furthermore, the BMI does not provide information on the localization of body fat, and additional anthropometric measurements, such as the waist and hip circumferences and subcutaneous skinfolds, have been commonly used to estimate regional adipose tissue distribution (68).

Anthropometric estimates such as the waist-to-hip ratio (WHR) and skinfold measurements have generated considerable evidence to support the notion that the localization of adipose tissue rather than the accumulation of total body fat is a critical correlate of metabolic disturbances that are significant risk factors for CVD (54,55,59,69–71). Therefore, several epidemio-

logical and metabolic studies published over the last two decades have indicated that the regional distribution of body fat was indeed the main factor involved in the relation of obesity to dyslipoproteinemias and CVD (37,38,54–56,69–90).

In this regard, Professor Jean Vague, from the University of Marseille, first proposed more than 50 years ago that body fat topography was a better correlate of the complications of obesity (diabetes, hypertension, CVD) than excess fatness per se (73). Vague defined the male type of fat distribution as “android obesity”, mostly characterized by an accumulation of adipose tissue over the trunk, whereas he referred to the common fat pattern of women as “gynoid obesity,” where adipose tissue accumulates mostly around the hips and thighs, this type of obesity being seldom associated with the common complications of excess fatness (73). However, it took more than four decades before these pioneering observations became widely accepted by the scientific community. During this period, the concept of adipose tissue distribution did not receive much attention, and only a few studies published in the 1960s examined this issue. In 1964, Albrink and Meigs (74) reported stronger correlations between plasma TG levels and trunk skinfolds than any other skinfold considered. Allard and Goulet (75) reached similar conclusions in the late 1960s. Although these studies showed associations between excess trunk fat and plasma TG levels, the concept of regional adipose tissue distribution only received serious consideration when prospective studies published in the 1980s indicated that excess abdominal fat was associated with an increased mortality rate in a manner which was independent of concomitant variation in total fatness as estimated by the BMI (72,76–78). These studies have shown that regional fat distribution, assessed by WHR or skinfolds, was associated with a higher incidence of diabetes and CVD, and with an increased mortality rate (76–78).

The related dyslipidemic state was an obvious possibility to explain the increased CVD risk associated with abdominal obesity, and several studies have examined the potential associations between abdominal fat accumulation and dyslipidemias. More specifically, it has been demonstrated that subjects characterized by a high accumulation of abdominal fat have elevated fasting plasma TG levels (80,82) and reduced plasma HDL cholesterol concentrations (69,80,83–85).

Studies for which HDL subfractions were measured revealed that the reduction in HDL cholesterol observed with excess abdominal fat was mainly attributed

to a decrease in the concentration of plasma HDL<sub>2</sub> cholesterol concentrations (83–87). In addition, it has been shown that in abdominal obesity, plasma HDL cholesterol levels were reduced to a greater extent than plasma HDL-apo A1 levels and that HDL were TG enriched (88). The presence of small HDL particles is another common feature of the dyslipidemic state of abdominal obesity (91,92).

Additional work has revealed that LDL particle concentration, composition and density are altered among subjects with a high WHR (85,93). Indeed, abdominal obesity has been associated with an increased proportion of small, dense, cholesteryl ester-depleted LDL particles (39,85,93). As discussed above, the small, dense LDL phenotype is also accompanied by higher concentrations of TG and lower levels of HDL cholesterol (39), alterations that are often found in CHD patients (89).

Abdominal obesity has also been reported to relate to alterations in indices of plasma glucose-insulin homeostasis. Indeed, prospective studies have shown that an excess of abdominal fat is associated with an increased risk of diabetes (79). Although the mechanisms linking abdominal obesity to type 2 diabetes are not fully understood, it appears that a preferential accumulation of adipose tissue in the abdominal region is associated with glucose intolerance, hyperinsulinemia, and insulin resistance which are metabolic conditions predictive of an increased risk of type 2 diabetes (70,71).

Using anthropometric measurements, several studies reported that upper body obesity is more prevalent in diabetic patients than in control subjects (90). Moreover, alterations in indices of plasma glucose-insulin homeostasis are frequently observed in abdominally obese patients (71,73,81,82). More specifically, the preferential accumulation of abdominal fat has been shown to be related to hyperinsulinemia in the fasting state as well as following a glucose load (70,71). Increased insulin secretion, insulin resistance, and decreased hepatic insulin extraction are common metabolic disturbances in abdominal obesity (71,94–96). These important metabolic events may explain the resulting hyperinsulinemia found in patients with an excess of abdominal fat. Furthermore, glucose intolerance or at least an increased plasma glucose response to a glucose load are frequently found in abdominally obese patients despite the presence of hyperinsulinemia confirming the presence of insulin resistance (70,71). These alterations in lipoprotein-lipid and insulin-glucose metabolism found in abdominally obese patients contribute to explain the high prevalence of CVD and type 2 diabetes in these subjects (97).

### III BODY FAT DISTRIBUTION AND DYSLIPIDEMIAS: IMPORTANCE OF VISCERAL ADIPOSE TISSUE

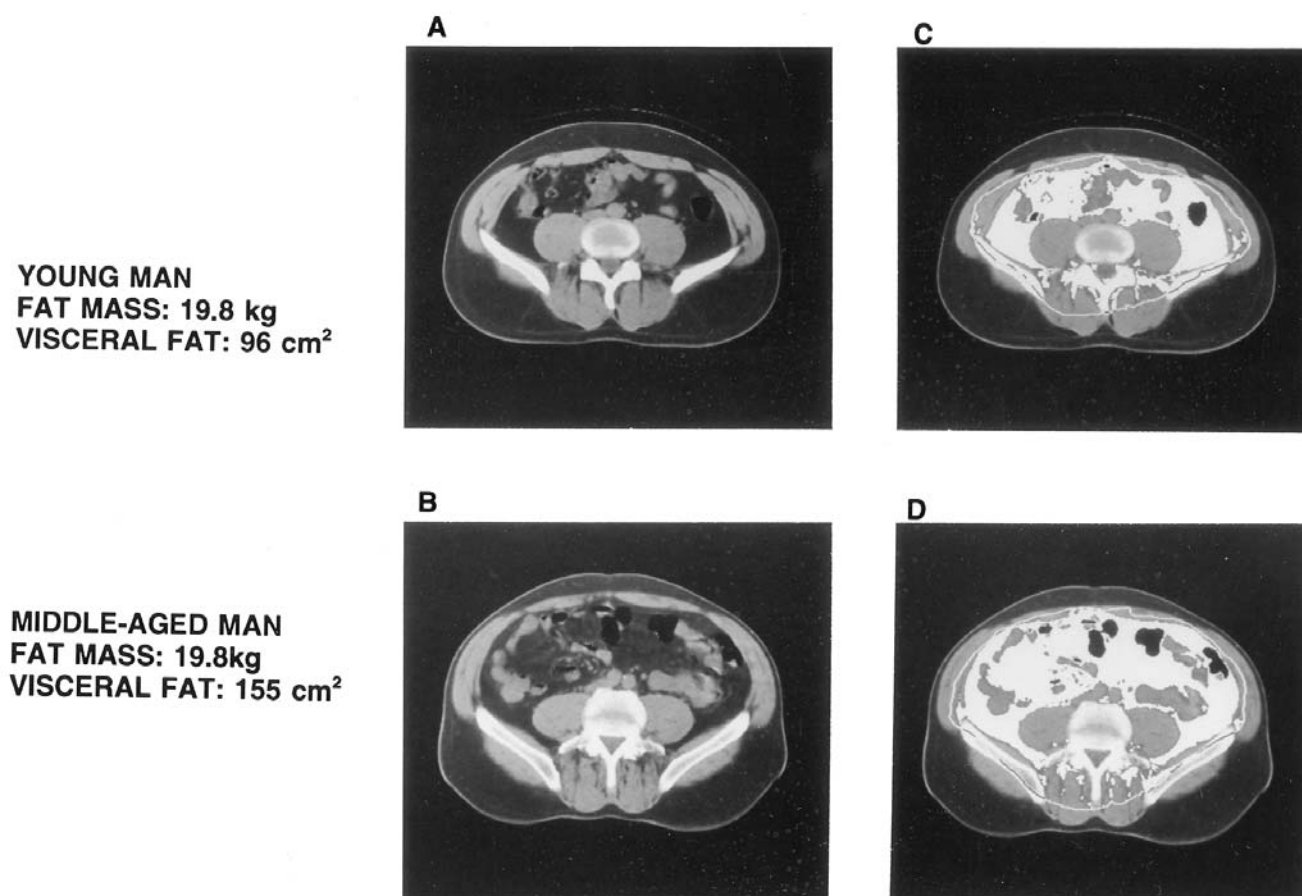

#### A Measurement of Visceral Adipose Tissue

The development in the 1980s of imaging techniques such as computed tomography (CT) has allowed the precise assessment of adipose tissue distribution (98–100). Using CT, one can easily distinguish adipose from lean tissues. Indeed, the attenuation scores generated by CT vary from -1000 (air) to +1000 (bone), depending on the level of absorption of emitted x-ray beams (100, 101). Studies that have examined the attenuation of tissues have established that the range of attenuation values (Hounsfield units, HU) for adipose tissue varies between -190 and -30 HU (100,101).

Computed tomography is also quite useful to assess precisely the amount of abdominal adipose tissue and is particularly helpful to distinguish the adipose tissue located in the abdominal cavity (the so-called intra-abdominal or visceral adipose tissue) from subcutaneous abdominal fat. When this procedure is performed, the subject is examined in the supine position with both arms stretched above the head (100,101). To measure subcutaneous and visceral abdominal adipose tissue areas, CT scans are usually performed between L4 and L5 vertebrae. Total adipose tissue areas are calculated by delineating the abdominal area with a graph pen and then computing total adipose tissue surface with an attenuation range of -190 to -30 HU (100,101). To measure the area of visceral adipose tissue, a line is drawn by passing through the muscle wall delineating the abdominal cavity (Fig. 4).

#### B Metabolic Disturbances Associated with Excess Visceral Adipose Tissue

Studies that have used this technique have reported that the amount of visceral adipose tissue is a critical correlate of the common metabolic complications found in obese patients. Fujioka and colleagues (102) have studied a heterogeneous group of obese patients and assessed cross-sectional areas of adipose tissue located subcutaneously or in the abdominal cavity (visceral adipose tissue). They reported that individuals with a preferential accumulation of abdominal visceral fat showed higher plasma glucose responses following an oral glucose challenge and higher fasting plasma TG levels than individuals with similar BMI values but characterized by an excess of subcutaneous abdominal fat (102–104). Several cross-sectional studies have

**Figure 4** Cross-sectional abdominal adipose tissue areas measured by CT at L4-L5 in a middle-aged man (B,D) and a young man (A,C) with similar total body fat mass values. The visceral adipose tissue, delineated by drawing a line within the muscle wall surrounding the abdominal cavity, is highlighted (C,D).

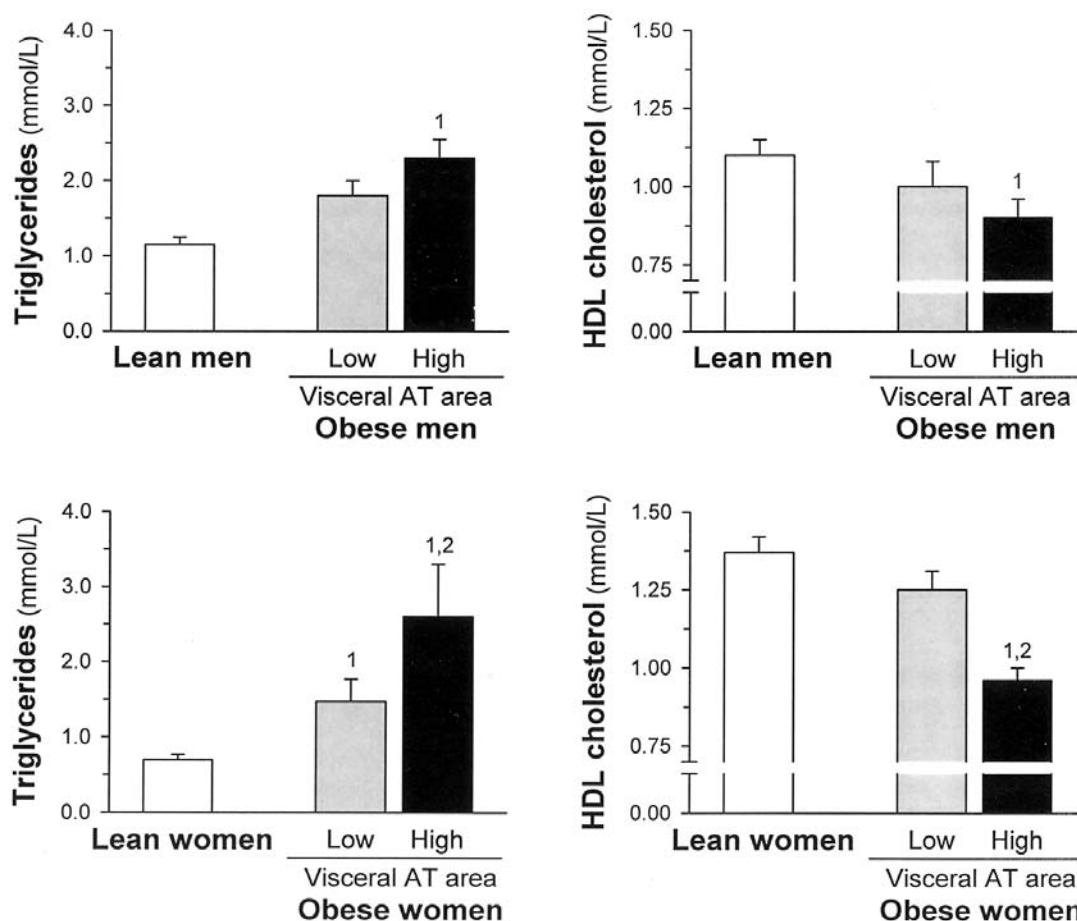

also consistently found that an excess of abdominal visceral adipose tissue was associated with substantial alterations in indices of plasma glucose-insulin homeostasis and in plasma lipoprotein-lipid levels (86,87, 105–108).

We have examined the potential relationships between visceral adipose tissue accumulation and plasma lipoprotein levels in obese premenopausal women (86) and found that the level of visceral adipose tissue was the best correlate of lipoprotein variables that are commonly used to predict the risk of CHD. Excess visceral adipose tissue was associated with increased apo B concentrations and low plasma HDL cholesterol levels (86). We have also quantified the independent contributions of obesity versus visceral adipose tissue accumulation by comparing obese individuals with either low or high levels of visceral adipose tissue to a group of lean subjects (Fig. 5). As shown in Figure 5, the

only significant difference noted between the obese subjects with low levels of visceral fat and lean individuals was a moderate increase in plasma TG levels in the obese group, whereas obese individuals with high levels of visceral fat showed important alterations in their plasma lipoprotein profile compared to lean controls. Consequently, obese individuals with a high level of visceral adipose tissue may represent the subgroup of obese individuals potentially at highest risk for CHD (69,108).

We have also compared indices of plasma glucose-insulin homeostasis among these three groups of subjects (107–109) and found that obese subjects with high levels of visceral adipose tissue had a higher glycemic response to a glucose challenge in the presence of hyperinsulinemia, reflecting an insulin resistant state (Fig. 6). In contrast, obese subjects with a low accumulation of visceral adipose tissue showed normal glucose

**Figure 5** Plasma triglyceride and HDL cholesterol concentrations in nonobese subjects and in subgroups of obese subjects matched for body composition but having either low or high levels of visceral adipose tissue (AT) determined by computed tomography. <sup>1</sup>Significantly different from nonobese subjects,  $P < .05$ . <sup>2</sup>Significantly different from obese subjects with low levels of visceral adipose tissue,  $P < .05$ . (Adapted from Ref. 179.)

tolerance and only a slight elevation in plasma insulin levels. These analyses and group comparisons were performed in both men and women, and similar conclusions were reached (107–109). Thus, these results indicate that obesity per se is associated with moderate metabolic alterations whereas excess visceral adipose tissue accumulation is related to substantial disturbances in indices of plasma glucose-insulin homeostasis which are predictive of an increased risk of type 2 diabetes.

Using CT, it has been reported that marked gender differences exist regarding visceral adipose tissue accumulation. For instance, we found that men have almost twice the amount of abdominal visceral adipose tissue for a given body fat mass as premenopausal women

(Fig. 7) (110). Furthermore, we have studied the potential contribution of gender differences in visceral adipose tissue accumulation to the sex dimorphism found in CVD risk variables (111). After control for the gender dimorphism in visceral adipose tissue accumulation, it was found that most of the differences observed in indices of plasma glucose-insulin homeostasis and in plasma lipoprotein-lipid profile were no longer significantly different between men and women (111), suggesting that the greater CVD risk noted in men compared to premenopausal women may be partly due to the preferential accumulation of visceral adipose tissue in male subjects.

Finally, in an attempt to examine whether there could be a threshold of visceral adipose tissue accumu-

**Figure 6** Plasma glucose and insulin concentrations in fasting state (–15 and 0 min) and during oral glucose tolerance test in obese women with high (●) or low (○) levels of visceral adipose tissue ( $n = 10$  subjects/group) and in a sample of lean women (□) ( $n = 25$ ). <sup>1</sup>Significantly different from (□). <sup>2</sup>Significantly different from (○),  $P < .05$ . (Adapted from Ref. 109.)

lation above which complications may be found, several variables predictive of CVD and type 2 diabetes were compared among samples of young adults and premenopausal women who were divided into quintiles formed on the basis of their cross-sectional visceral adipose tissue area measured by CT. Figure 8 shows that in both men and women, a value  $<100 \text{ cm}^2$  was associated with a rather favorable risk profile (112). However, a cross-sectional visceral adipose tissue area of  $130 \text{ cm}^2$  and above was associated with a substantial deterioration in the cardiovascular risk profile (112).

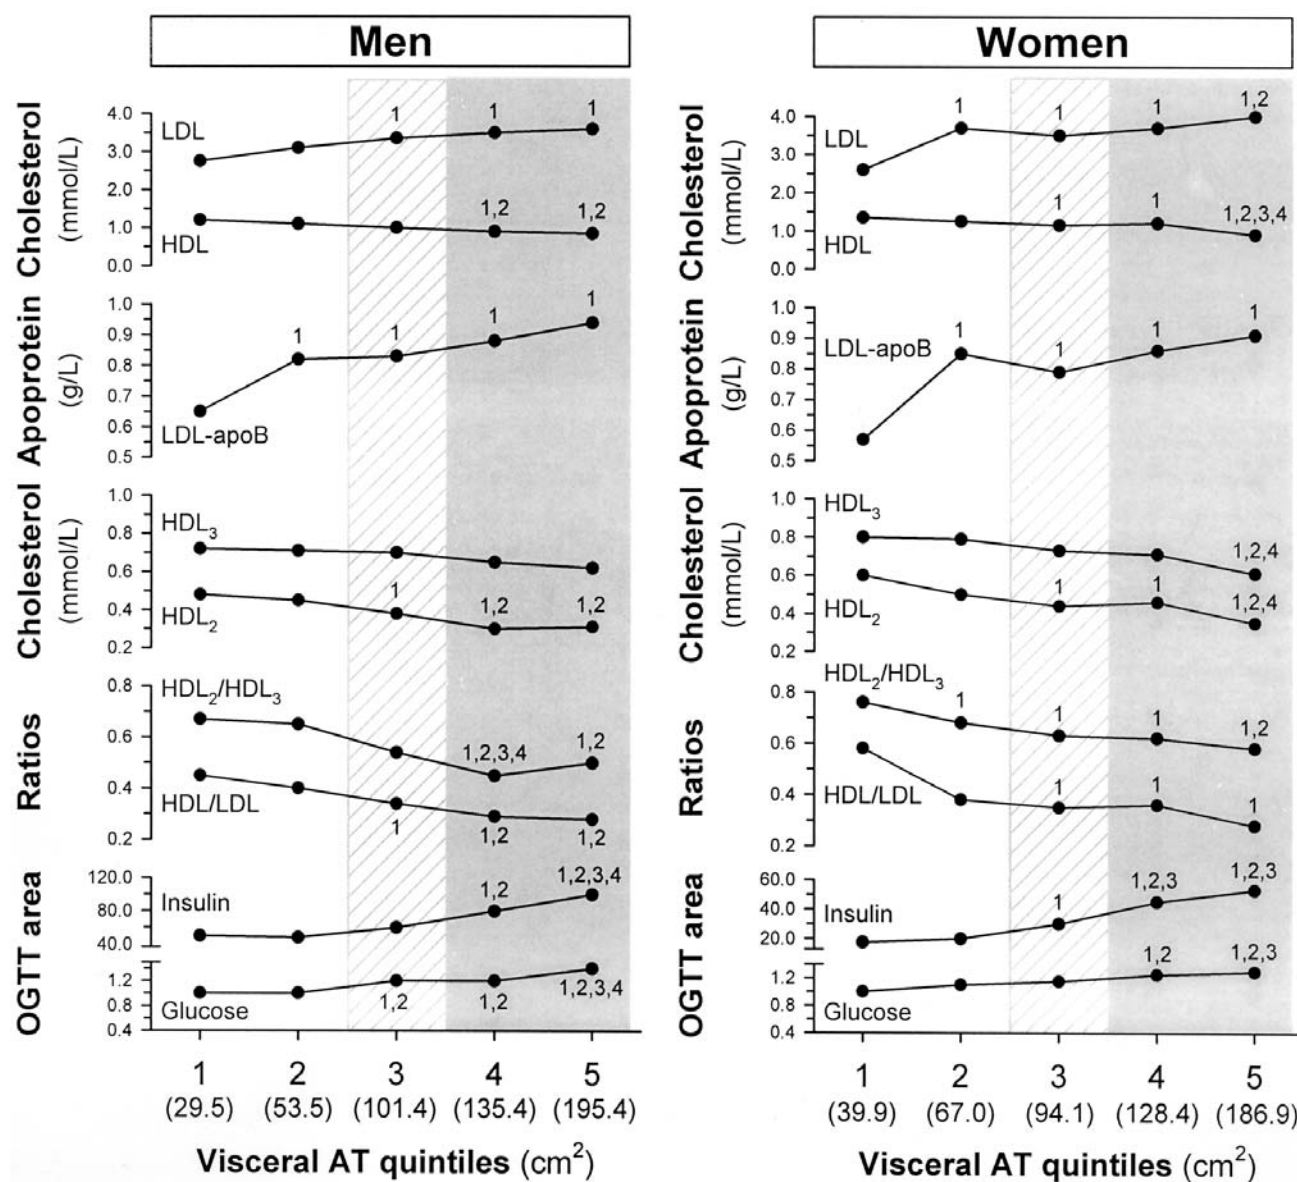

### C Postprandial Hyperlipidemia: Another Feature of Visceral Obesity

Analysis of lipid and lipoprotein metabolism has long been limited to the fasting state, i.e., when TG metabolism is reduced and lipid transport is presumably at equilibrium. However, considering meal frequency in Western populations, humans spend most of the day under postprandial conditions and thus, dietary fat tolerance should receive greater attention. Interest for the study of postprandial lipoprotein metabolism has been renewed since Zilversmit (113) hypothesized that chylomicron remnants, following enrichment in cholesterol esters, could be involved in the development of atherosclerosis. This theory has been given further support, and many factors have already been reported to modulate postprandial TG-rich lipoprotein metabolism. For instance, age (114,115), male gender (114, 116,117), a high-fat diet (118), alcohol consumption (119–121), and lack of exercise (122–125) have all been associated with an exaggerated and prolonged postprandial lipemia.

Obesity is associated with numerous metabolic disturbances that have been extensively described earlier in this chapter. In addition to alterations in lipoprotein-lipid metabolism in the fasting state, obese individuals have been characterized by a greater plasma TG response following ingestion of a fatty meal (126).

**Figure 7** Relation of total body fat mass to abdominal visceral adipose tissue (AT) area measured by computed tomography in 89 men and 75 premenopausal women. Both correlations were significant at  $P < .0001$ . (Adapted from Ref. 110.)

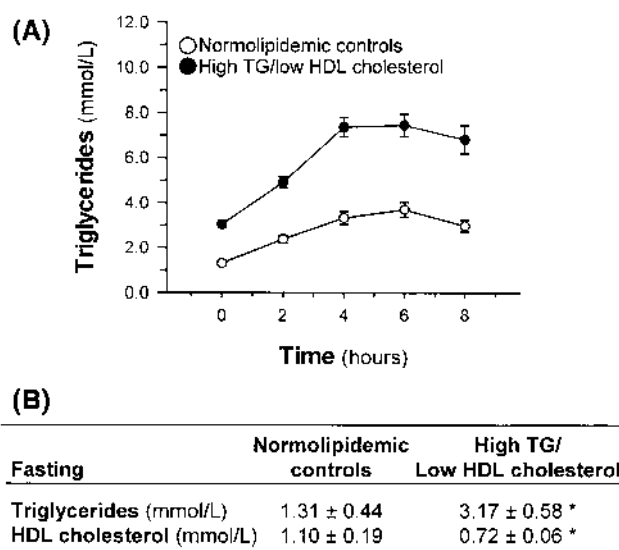

**Figure 8** Relations of quintiles of abdominal visceral adipose tissue (AT) area to variables predictive of type 2 diabetes and CVD risk in samples of 115 men and 72 women, respectively. This figure shows that visceral AT areas  $>100 \text{ cm}^2$  are associated with moderate but significant metabolic changes, whereas visceral AT areas  $>135 \text{ cm}^2$  in men and  $128 \text{ cm}^2$  in women are clearly associated with further metabolic deteriorations that suggest an increased risk of type 2 diabetes and CVD. 1, 2, 3, or 4 significantly different from quintiles 1, 2, 3, and 4, respectively ( $P < .05$ ). Apo: apolipoprotein; OGTT: oral glucose tolerance test. (From Ref. 112.)

Although this postprandial hypertriglyceridemic state has been suggested to result from delayed clearance and/or catabolism of newly synthesized intestinal TG-rich lipoproteins, namely chylomicrons and their remnants (126), the fact that the postprandial increase of retinyl ester, a marker of TG-rich lipoproteins produced by the

intestine, was of lesser magnitude compared to the TG response also suggested that a significant proportion of the postprandial TG response was due to endogenous hepatic VLDL production. In recent years, the role of abdominal fat accumulation in this metabolic alteration has been underlined. For instance, a preferential

accumulation of fat in the abdominal region has been shown to be a better correlate of the impairment of postprandial TG-rich lipoprotein metabolism than excess fatness per se (127–130). In addition, we have shown that the intra-abdominal component of abdominal fat deposition was probably responsible for this deterioration (130). The importance of both intestinally and hepatically derived TG-rich lipoproteins in this postprandial hypertriglyceridemic state of abdominally obese individuals has also been underlined (129–131). Furthermore, the detrimental impact of visceral obesity was recently documented to explain the greater postprandial TG levels found in men compared to women (116). For instance, we have shown that when matched for visceral adipose tissue accumulation, men and women show comparable postprandial lipemic responses (116). Thus, and as shown in Figure 9, viscerally obese patients are not only characterized by a fasting dyslipidemic state, but they also display an exaggerated postprandial TG response and a prolonged postprandial hyperlipidemic state compared to nonobese normolipidemic subjects.

**Figure 9** Plasma triglyceride (TG) levels measured for 8 hours following the consumption of a standardized breakfast with a high lipid content (60 g dietary fat/m<sup>2</sup> of body surface area) in a sample of lean normolipidemic subjects as well as in a sample of viscerally obese patients with the fasting high TG/low HDL cholesterol dyslipidemia. \*Significantly different from normolipidemic controls,  $P < .0001$ . (Adapted from Ref. 131.)

#### D Atherogenic Metabolic Profile of Visceral Obesity: Beyond Insulin Resistance and Related Dyslipidemias

Although it has become clear that visceral obesity is associated with diabetogenic and atherogenic metabolic alterations, studies have shown that additional metabolic disorders could explain the increased risk of CHD in these individuals. For instance, visceral obesity has been found to be associated with an impaired fibrinolysis and with an increased concentration of prothrombotic molecules such as plasminogen activator inhibitor-1 (PAI-1) (132). Recent results have also indicated that visceral obesity is characterized by a state of chronic inflammation as revealed by increased plasma levels of C-reactive protein (CRP) (133–135) likely to result from the greater cytokine production (interleukin (IL)-6, tumor necrosis factor (TNF)- $\alpha$ ) of the expanded visceral adipose depot (133,135). Thus, visceral obesity is associated with insulin resistance and with a dyslipidemic, prothrombotic, and inflammatory profile that can contribute substantially to increase the risk of an acute coronary event (136).

#### IV DOES THE ATHEROGENIC DYSLIPIDEMIA OF VISCERAL OBESITY REFLECT A CAUSE-EFFECT RELATIONSHIP?

It has been suggested that enlarged omental adipocytes, which have been shown to display a high lipolytic activity, poorly inhibited by insulin (54,70,71,137), contribute to a greater flux of free fatty acids (FFA) toward the liver through the portal circulation. As shown in Figure 10, high portal FFA levels are associated with reduced hepatic insulin extraction (138,139) and lead to an increased VLDL synthesis and apo B production (55,137). Moreover, it has been suggested that increased lipid oxidation is associated with impaired glycolysis (140,141) and with a decrease in glycogen synthase activity (142). Furthermore, this elevated lipid oxidation provides precursors for gluconeogenesis (143). Thus, the evidence available suggests that insulin action is impaired in subjects displaying high FFA levels and that compensatory hyperinsulinemia is thus required to regulate plasma glucose levels in insulin resistant subjects (33).

Lipoprotein lipase is an enzyme responsible for the catabolism of TG-rich lipoproteins, and its activity has been found to be correlated with metabolic alterations

and decreased degradation (through reduced LPL activity) are associated with an increased transfer of TG from VLDL to LDL or HDL particles (87,88) in exchange of LDL and HDL cholesteryl esters, leading to the TG enrichment of LDL and HDL. Such TG enrichment is associated with a reduced cholesterol content of HDL. Furthermore, TG-rich LDL and HDL particles represent good substrates for the enzyme HTGL, ultimately generating an atherogenic dyslipidemic phenotype including small, dense LDL and HDL particles (55,92). Thus, reciprocal changes in LPL and HTGL activities are important correlates of dyslipidemias found in an insulin resistant state associated with visceral obesity.

The mechanisms leading to *in vivo* insulin resistance are not fully understood, and it is also known that impaired insulin action can be present in both obese and nonobese subjects (33). These observations suggest that insulin resistance is a heterogeneous condition and provide further evidence that some genetic factors are likely to be involved. Studies conducted among insulin-resistant or type 2 diabetic subjects have shown that the presence of a familial history of diabetes may alter the relationship of abdominal fat accumulation to indices of plasma glucose-insulin homeostasis (146,147). We have previously reported that in subjects with a similar level of deterioration in plasma glucose-insulin homeostasis, those who displayed a positive familial history of diabetes had lower levels of abdominal fat than subjects without a familial history of diabetes (147). These results suggest that the presence of genetic susceptibility reduces the threshold of abdominal fat above which metabolic alterations predictive of an increased type 2 diabetes risk are observed. Thus, in abdominally visceraally obese patients, high FFA concentrations (increased lipolysis of the visceral depot), decreased LPL activity and reduced insulin sensitivity may lead to metabolic changes that are ultimately involved in the development of insulin resistance, glucose intolerance, hyperinsulinemia, dyslipoproteinemia, type 2 diabetes, and CVD.

In addition to the impaired FFA metabolism hypothesis briefly reviewed above, it has been suggested that abdominal obesity is associated with altered sex steroid levels. Results that have crudely assessed body fat distribution by the WHR have reported low levels of sex hormone binding globulin (SHBG) concentrations and high levels of free testosterone in women with excess abdominal fat (70,148–151). Moreover, the altered sex steroid concentrations observed in abdominally obese women have also been associated with variations of *in vivo* insulin sensitivity (70,150). Studies have also shown

that the hyperinsulinemic state of abdominal obesity was partly attributed to a reduction in the hepatic extraction of insulin (148), the latter phenomenon being associated with lower SHBG concentrations. Furthermore, a reduced hepatic insulin extraction has also been related to high free testosterone levels in women (148). Thus, the associations of steroid levels with metabolic disturbances have been shown to be partly independent of the concomitant variation in adipose tissue distribution. It has also been suggested that although there is clearly an independent association between visceral fat accumulation and metabolic alterations, the dyslipidemic state observed in abdominally obese women could also partially be due to the concomitant alterations in the sex steroid profile (70).

In men, however, the associations among sex steroids, visceral obesity, and the metabolic profile are quite different from those noted in women. As opposed to abdominally obese women, visceral obesity in men is rather associated with a reduction of plasma testosterone levels (151,152). It is also not well established whether reduced levels of androgenic steroids are independently associated with an excess abdominal visceral fat accumulation after control for the concomitant variation in the amount of total body fat (152). Furthermore, the alterations found in steroid hormone levels have been found to be significantly correlated with glucose intolerance (153) and with the dyslipidemic state observed in visceral obesity (154,155). It is also relevant to note that, after controlling for variations in testosterone, the relationship between the amount of visceral adipose tissue to insulin resistance and to dyslipidemia remained significant (153,156).

In addition, the potential role of glucocorticoids on the regulation of lipid metabolism in visceral obesity must be considered (157–159). It has been proposed that the insulin-resistant state observed in subjects with excess visceral adipose tissue is partly the consequence of altered glucocorticoid levels (157–159). In this regard, environmental stress can induce an activation of the hypothalamic-pituitary-adrenal axis thereby increasing cortisol production (160). Visceral adipose cells have been reported to have the highest density of glucocorticoid receptors (161,162) in comparison to adipocytes from other fat depots, and this could explain the greater sensitivity of visceral adipose tissue to stressor agents. Furthermore, the metabolic effects of glucocorticoids (157) are in accordance with the alterations observed in visceral obesity (55,69,157). Indeed, glucocorticoids stimulate VLDL and apo B production, reduce the activity of LDL receptors, and induce insulin resistance (157).

Recently, studies have suggested that patients with growth hormone (GH) deficiencies also show the features of the metabolic syndrome including an increased visceral adipose tissue accumulation (163–166). In this regard, some intervention studies have suggested that GH replacement in relatively deficient GH patients could improve the features of the metabolic syndrome including changes in body fat distribution and visceral adipose tissue loss (163,165–167). This promising area represents a fertile area of investigation that will require further studies.

Finally, it has also been shown that adipose tissue was a remarkable endocrine organ beyond its lipid storage/mobilization functions. For instance, the expanded visceral adipose depot is a site of synthesis of pro-thrombotic molecules such as PAI-1 and of cytokines (leptin, IL-6, TNF- $\alpha$ ). Resulting elevations in plasma IL-6 and TNF- $\alpha$  concentrations stimulate CRP synthesis by the liver and these cytokines therefore contribute to the inflammatory profile recently reported in viscerally obese patients (133,135). Thus, we have suggested that in addition to the model linking the expanded visceral adipose depot to an atherogenic dyslipidemic state, the pro-thrombotic and inflammatory profile of viscerally obese patients could also be linked to the intrinsic and peculiar activity of the visceral adipocytes (Fig. 11). In summary, the dyslipidemic state of visceral obesity

**Figure 11** Model linking the expanded visceral adipose depot as an endocrine organ releasing cytokines contributing to the inflammatory component of coronary artery disease by the production of an unstable plaque with a thin fibrous cap and prone to rupture. Under this model the viscerally obese patient is at markedly elevated risk for an acute coronary syndrome as predicted by the increased levels of inflammation markers. CRP: C-reactive protein; IL-6: interleukin-6; TNF- $\alpha$ : tumor necrosis factor- $\alpha$ .

results from complex metabolic and hormonal interactions that lead to insulin resistance and to an increased CVD risk (Fig. 10).

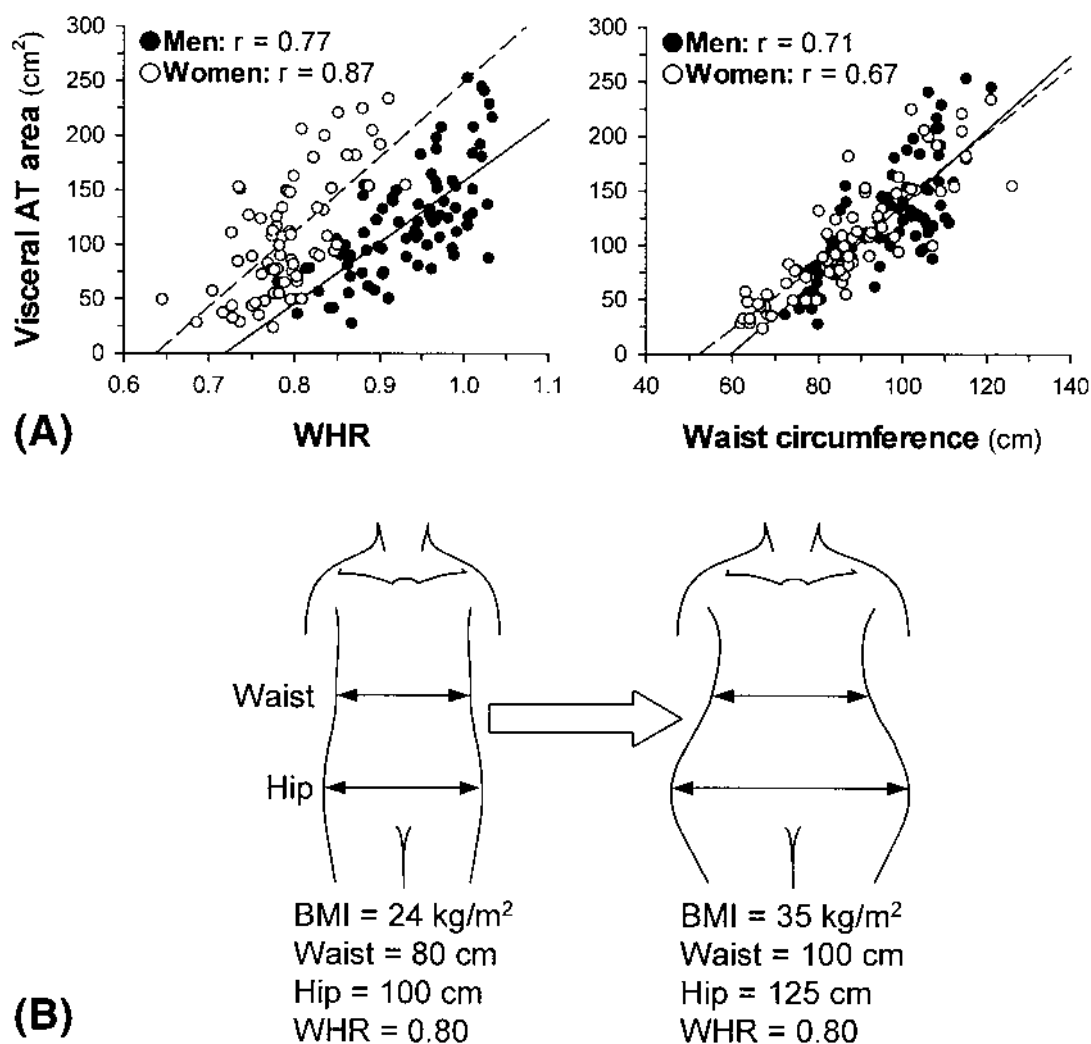

## V VISCERAL OBESITY, DYSLIPIDEMIAS, AND CHD: CLINICAL IMPLICATIONS

From the evidence reviewed, the detection of the subgroup of obese patients at risk for complications associated with excess visceral adipose tissue is clinically important. Thus, an adequate estimation of visceral adipose tissue accumulation is of great relevance to better quantify the patient's risk of CVD. Although CT is very accurate and reliable, it is not accessible to most clinicians, and it was relevant to develop approaches in order to offer simple tools for the detection, prevention, and treatment of visceral obesity.

### A Is Anthropometry an Appropriate Alternative to CT?

Numerous studies have examined the correlations between anthropometric measurements and cross-sectional visceral adipose tissue areas measured by CT (168,169,171). Until recently, the WHR had generally been considered as the most relevant variable in the assessment of visceral obesity (76–85), this ratio being often used in prospective and metabolic studies. Although the use of WHR has contributed to highlight the importance of body fat distribution, we have reported that visceral adipose tissue accumulation showed better correlations with the waist circumference alone than with the WHR (172). Figure 12 shows that the relation of visceral adipose tissue area to the waist girth was stronger than for the WHR, especially in women. Furthermore, the relationship between waist circumference and visceral adipose tissue was found to be similar in men and women. Moreover, waist circumference also appears to be a good correlate of total body fatness and therefore provides a better index of abdominal obesity than the WHR alone, which is a weak correlate of total adiposity (172).

For example, a nonobese woman with small hips may have a WHR value which could be similar to an obese woman with a large accumulation of abdominal fat but with also a substantial deposition of fat at the hip level (Fig. 12). Thus, despite similar WHR values in these two subjects, the obese women would have a much greater accumulation of visceral adipose tissue than the non-obese women despite the fact that their WHR are simi-

**Figure 12** (A) Relation of waist-to-hip ratio (WHR) or waist circumference to abdominal visceral adipose tissue (AT) areas measured by computed tomography in men and women. (B) Misleading evaluation provided by the WHR in two women with markedly differing levels of total body fat and of visceral AT. This example illustrates the notion that the WHR is an index of the relative accumulation of abdominal fat whereas waist circumference provides a better index of the absolute amount of abdominal adipose tissue. BMI: body mass index. (Adapted from Refs. 172,178.)

lar. Consequently, the use of WHR alone can be quite misleading, whereas a high waist girth obviously indicates that excess abdominal fat and obesity are simultaneously present. Indeed, the waist circumference is positively correlated with both an accumulation of total body fat and an elevated deposition of visceral adipose tissue (172). In this context, we have proposed that the waist circumference provides a valuable index of the absolute amount of abdominal fat compared to the WHR, which rather reflects relative abdominal adipose

tissue deposition (172). On that basis, the waist circumference has now been recognized as an index of abdominal fat in the NCEP-ATP III guidelines (36).

#### **B Hypertriglyceridemic Waist: A New Phenotype Defining the High-Risk Abdominally Obese Patient**

Despite the fact that waist circumference is a better predictor of visceral adipose tissue accumulation (espe-

cially over time) than BMI, abdominally obese individuals remain a heterogeneous group of patients. We were interested in the development of a simple screening approach to help physicians and health professionals identify high-risk abdominally obese patients with the features of the insulin resistance/metabolic syndrome. In a recent study, we reported that waist circumference was the simplest and best correlate of plasma insulin and apo B levels, whereas another simple parameter, fasting TG concentration, was the best predictor of LDL size (40). Sensitivity and specificity analyses revealed that the best discrimination of carriers/noncarriers of this atherogenic metabolic triad (elevated insulin and apo B levels as well as small, dense LDL particles) was obtained when using cutoff points of 90 cm for waist circumference and 2.0 mmol/L for TG in a sample of middle-aged men (Fig. 13). For instance, middle-aged men with a waist <90 cm and fasting TG levels <2.0 mmol/L had a low chance (10%) of being carriers of the triad. However, >80% of men with a waist girth ≥90 cm and TG levels ≥2.0 mmol/L had all features of the metabolic triad (40). Thus, we believe that health professionals have access to a simple and inexpensive screening test to identify a high-risk form of abdominal obesity. As there are no prospective data available in women to quantify the CHD risk associated with the metabolic triad, there is an urgent need to validate this approach in women. It should also be emphasized that there are differences in susceptibility to develop visceral obesity and related complications (diabetes, hypertension, and CHD) among ethnic groups, and our approach should only be considered as valid for Caucasian men. Specific cutoffs are likely to be obtained for instance for our Native American population as well as for the African-American and South Asian populations.

| Waist circumference | + | Fasting triglycerides | Prevalence of metabolic syndrome |
|---------------------|---|-----------------------|----------------------------------|
| < 90 cm             | + | < 2.0 mmol/L          | ~ 10%                            |
| ≥ 90 cm             | + | ≥ 2.0 mmol/L          | ~ 80%                            |

**Figure 13** Description of two phenotypes predictive of either a very low or a high risk of being characterized by the atherothrombotic, inflammatory profile of the metabolic syndrome.

## VI CONCLUSION. ASSESSMENT AND MANAGEMENT OF ATHEROGENIC DYSLIPIDEMIAS IN OBESE PATIENTS: WAIST GIRTH AS A VITAL SIGN

From the epidemiological and metabolic evidence available, there is no doubt that abdominal obesity is an important risk factor for the development of dyslipidemias and CVD. Several prospective studies have shown that abdominal obesity is associated with an increased mortality rate related to CVD (72,76–78,173–175). However, it is also important to acknowledge the notion that no intervention study has shown that reducing obesity and the amount of abdominal fat would lead to a reduction in the incidence of CVD and related mortality. To the best of our knowledge, the only ongoing project on this issue is the study of Swedish Obese Subjects (SOS study) (176), but these results will only apply to the question of weight loss resulting from the surgical treatment of very obese patients. However, it must be recognized that there is a considerable amount of literature that has indicated that reducing body weight and lowering the amount of abdominal fat is associated with major improvements in the CVD risk profile including reduction in blood pressure, improvement in plasma lipoprotein-lipid levels, and an increase in insulin sensitivity leading to a reduction in plasma insulin levels and to an improvement of glucose tolerance (112).

As obesity is often associated with metabolic complications causing prejudice to health, it has been suggested that obesity should be considered as a disease. However, because obesity is defined on the basis of the BMI, some healthy individuals with BMI values ≥30 are then classified as high-risk subjects (with a disease) despite the presence of a normal metabolic risk profile. This problem may explain the generally unimpressive findings reported with the pharmacotherapy of obesity, as these studies have largely included low-risk, normolipidemic obese women with a normal metabolic risk factor profile (177). Nevertheless, on the basis of the substantial metabolic improvements that can be generated by a 5–10% weight loss (56,112), the importance of targeting weight loss in high-risk visceraally obese patients with an atherogenic dyslipidemic state and identified by the hypertriglyceridemic waist phenotype rather than by the BMI should be emphasized in clinical practice (178). In this high-risk obesity phenotype, the benefits of pharmacotherapy may outweigh the potential hazards of drug therapy—a possibility that needs to be urgently tested in randomized weight loss trials.

Therefore, as for the treatment of numerous additional complications of obesity, the assessment and management of CVD risk in obese patients needs to go beyond considering only body weight as a therapeutic target. Regarding the treatment of obese dyslipidemic patients, randomized trials using lipid-lowering drugs have all shown the benefits of the pharmacotherapy irrespective of the initial patient characteristics (11–16). As most of these studies have also included overweight/obese patients, it is likely that the obese dyslipidemic patient will benefit from the pharmacotherapy of his/her dyslip-

idemic state either with a statin (if LDL cholesterol concentrations are elevated) or with a fibrate (in the event that HDL cholesterol levels are low). Therefore, it is important to treat the consequences of abdominal obesity in a high-risk dyslipidemic patient with CHD, as the treatment of the complications will generate clinical benefits. However, the risk of a first or recurrent CHD event associated with the management of atherogenic dyslipidemic states has been reported to be reduced by ~30%, which indicates that a substantial proportion of patients on pharmacotherapy for their dyslipidemic

**Figure 14** Potential benefits of moderate (5–10%) weight loss in a high-risk patient with the cluster of atherothrombotic, inflammatory metabolic abnormalities associated with hypertriglyceridemic waist. Weight loss in abdominally obese patients is associated with selective mobilization of diabetogenic and atherogenic visceral adipose tissue. Even a 5–10% weight loss is associated with preferential mobilization of visceral adipose tissue, leading to simultaneous improvement in all metabolic markers of coronary heart disease (CHD) risk. Thus, simultaneous metabolic improvements associated with mobilization of visceral adipose tissue may contribute to substantially reducing the risk of an acute coronary event in high-risk patients. (Adapted from Ref. 178.)

state remain nevertheless at high risk for CHD. In this context, it is proposed that CHD risk in the obese dyslipidemic patient will not be optimally managed until abdominal fat accumulation and waist reduction are considered as therapeutic targets (178). On that basis, we have proposed that waist circumference should be considered as a vital sign and incorporated in the assessment algorithm of all patients. Such recommendation has now been endorsed by the NCEP-ATP III guidelines, which recognize waist circumference as a key feature of the metabolic syndrome (36).

Finally, and as shown on the concluding last figure (Fig. 14), we believe that the reported preferential mobilization of visceral adipose tissue observed with a moderate weight loss of 5–10% (56,112) is likely to explain the greater impact of such moderate weight loss on the atherothrombotic, inflammatory profile of abdominally obese dyslipidemic patients. Again, randomized trials are needed to quantify the true impact of a selective loss of abdominal fat on the absolute and relative risk of coronary heart disease in this high-risk but prevalent subpopulation of abdominally obese dyslipidemic patients.

## ACKNOWLEDGMENTS

The work of the authors reviewed in this chapter has been supported by the Canadian Institutes of Health Research and by the Canadian Diabetes Association. Jean-Pierre Després is chair professor of human nutrition, lipidology and prevention of cardiovascular diseases, which is supported by Pfizer, Provigo, and the Foundation of the Québec Heart Institute.

This work was supported by the National Institutes of Health Program Project grant HL18574 from the National Heart, Lung and Blood Institute, a grant from the National Dairy Promotion and Research Board, and administered in cooperation with the National Dairy Council, and was conducted at the Ernest Orlando Lawrence Berkeley National Laboratory.

## Obesity and Blood Pressure Regulation

**Albert P. Rocchini**

University of Michigan, Ann Arbor, Michigan, U.S.A.

### I INTRODUCTION

Obesity is an independent risk factor for the development of both hypertension and cardiovascular disease. This chapter will summarize: techniques for measuring blood pressure in obese individuals and the effect of obesity on these measurements; the evidence that substantiates that obesity is an independent risk factor for the development of hypertension; an explanation of how obesity may result in the development of hypertension; a brief summary of other cardiovascular abnormalities associated with obesity; and finally a brief summary of how to manage the hypertensive obese individual.

### II MEASUREMENT OF BLOOD PRESSURE IN OBESE INDIVIDUALS

For years, physicians believed that the high blood pressure observed in many obese individuals was related to a measurement error. The indirect method of measuring blood pressure usually results in an overestimation of both systolic and diastolic blood pressure. The overestimation of blood pressure is due, in part, to the fact that pressure measured by the cuff and sphygmomanometer is not just the force required to occlude the brachial artery but also includes the force required to compress the soft tissues of the arm. In the case of obesity, the increased subcutaneous fat present in the

upper arm imposes a greater resistance to compression and therefore a higher cuff inflation pressure. Most of the effects of obesity on the indirect measurement of blood pressure can be corrected by using an appropriate size blood pressure cuff. Although, compared with intra-arterial measurements of blood pressure, the indirect method is less precise, nevertheless, when properly measured, elevated indirect blood pressure readings are a reliable method for diagnosing hypertension. The major errors encountered in the measurement of blood pressure include cuff size, type of instrumentation for measuring blood pressure, and observer errors.

#### A Cuff Size

The selection of an appropriate-size compression cuff is critical to obtaining accurate reading. The cuff consists of an inflatable bladder with a cloth cover. The dimensions of the inner bladder, not the size of the cover, determine cuff size (Fig. 1). The bladder must be the correct width for the circumference at the mid point of the upper arm (Table 1). A bladder that is too small will cause a falsely high pressure. The bladder should be wide enough to cover ~75% of the upper arm between the top of the shoulder and the olecranon. The length of the bladder also influences the accuracy of measurements. A bladder length that is roughly twice the width is ideal and should result in the cuff nearly encircling the arm. If a question arises as to which of two cuffs is appropriate, a cuff that is slightly wider and longer than

**Figure 1** Schematic representation of a blood pressure cuff.

needed should be chosen. It is unlikely that slightly too large a cuff will mask hypertension, but a cuff that is too small will lead to an overestimate of blood pressure.

### B Types of Equipment for Indirect Measurement of Blood Pressure

Physicians have taken reliable blood pressure measurements for nearly 90 years with a compression cuff, sphygmomanometer, and stethoscope. The major errors associated with the use sphygmomanometer and stethoscope relate to calibration of the manometer, position of the arm (if the arm is below “heart level,” due to hydrostatic pressure, a falsely elevated blood pressure will be recorded), and the experience and training of the observer.

In order to eliminate observer errors automated blood pressure devices were developed. Most of these devices use the oscillometric technique. The oscillometric technique involves analysis of arterial “flutter,” the lower-frequency oscillations that occur, with each heartbeat, under an occluding cuff between the systolic

and diastolic pressures. A sensitive transducer attached to the cuff detects the flutter by selectively amplifying the oscillations and rejecting most artifacts. In general, these devices more reliably predict systolic than diastolic blood pressure.

### C Observer Errors

An observer may record the blood pressure inaccurately because of hearing impairments, inattention, carelessness, or subconscious bias. An example of such bias is “digit preference,” a well-documented phenomenon resulting in recording pressures ending with zero or five (i.e. 120 or 125 systolic or 80 or 85 diastolic) more often than expected by chance. The observer should be taught that systolic pressure is the point at which initial Korotkoff sounds are audible for two consecutive heart beats (phase I). Diastolic blood pressure should be measured at the pressure at which Korotkoff sounds disappear (phase V). With appropriate training observer errors can be greatly reduced.

### D Summary

Although the indirect method of blood pressure measurement may be imprecise in the obese individual, if appropriate care is taken to use a trained observer, a large enough blood pressure cuff, and a calibrated measurement device, reliable measurements of blood pressure can be made even in extremely obese individuals.

## III RELATIONSHIP BETWEEN OBESITY AND HIGH BLOOD PRESSURE

### A Epidemiological Studies Linking Obesity to Hypertension

The association between obesity and hypertension has been recognized since the early 1900s. Several large epidemiological studies documented the association

**Table 1** Recommended Bladder Dimensions for Blood Pressure Cuffs

| Circumference of arm at midpoint <sup>a</sup> (cm) | Name of cuff | Bladder width (cm) | Bladder length (cm) |
|--|--------------|--------------------|---------------------|
| 13–20  | Child        | 8                  | 13                  |
| 17–26  | Small adult  | 11                 | 17                  |
| 24–32  | Adult        | 13                 | 24                  |
| 32–42  | Large adult  | 17                 | 32                  |
| 42–50  | Thigh        | 20                 | 42                  |

<sup>a</sup> Midpoint of arm is defined as half the distance from the acromion to the olecranon.

between increasing body weight and an increase in blood pressure (1–12). Symonds (2) analyzed 150,419 policyholders in the Mutual Life Insurance Corporation and documented that systolic and diastolic blood pressure increased with both age and weight. In 1925, the Actuarial Society of America also documented a similar relationship in over 500,000 men (1). The Framingham Study (4) documented that the prevalence of hypertension in obese individuals was twice that of those individuals who were normal weight. This relationship held up in all age groups of both women and men. In the National Heart Association of Australia Risk Factor Prevalence Study (12), body mass index was independently associated with blood pressure level in both men and women. In that study, obesity was felt to be the cause of the hypertension in > 30% of the individuals. Stamler (2) found in a study of 1 million North Americans that the odds ratio of hypertension were significantly increased in obese compared to nonobese individuals (comparing obese with nonobese subjects the odd ratio for hypertension in subjects age 20–39 years was 2.42:1, and 1.54:1 in subjects age 40–64 years). Thus, a large number of population-based studies have documented a strong association between obesity and hypertension in both sexes, in all age groups, and for virtually every geographical and ethnic group.

### B Relationship of Weight Gain to Blood Pressure Level

There have been no studies in humans that have looked at the effect of weight gain on blood pressure. However, in the dog, it has been shown that weight gain is directly related to an increase in blood pressure. Cash and Wood in 1938 (13) demonstrated that weight gain caused dogs with renal vascular hypertension to further increase their blood pressure. More recently Rocchini et al. (14,15) found that normal mongrel dogs fed a high-fat diet gained weight and developed hypertension (Fig. 2). In these dogs the hypertension was associated with sodium retention, hyperinsulinemia, and activation of the sympathetic nervous system. Hall et al. (16) have also observed that weight gain in the dog is directly associated with an increase in arterial blood pressure.

### C Effect of Weight Loss on Blood Pressure Level

Weight loss is associated with a lowering of blood pressure. Haynes (17) reviewed the literature up to the mid-1980s on the relationship of weight loss to reductions in arterial pressure. He used strict criteria to examine only well-done studies and noted that there

**Figure 2** Weight, mean arterial pressure, and heart rate for six dogs fed a high-fat diet. With weight gain there is a significant increase in heart rate and blood pressure, and this is reversed with weight loss. (Adapted from Ref. 14.)

were only six studies available. Three of the six studies that met Haynes criteria demonstrated a clear effect of weight loss on lowering arterial pressure. Overall, many clinical trials that have been published since the late 1970s have clearly documented the blood pressure lowering effect of weight loss (17–31). However, one of the controversial aspects of these studies is whether the weight loss alone, independent of alterations in dietary sodium, was responsible for the observed reductions in blood pressure. Dahl (27) concluded that the reduced salt intake inherent in hypocaloric diets, rather than weight loss, was responsible for the lowering of blood pressure. Similarly, Fagerberg et al. (21) noted no decrease in blood pressure in individuals after weight loss using a 1230-calorie, unrestricted sodium diet; however, in another group of individuals, similar caloric restriction combined with a low-sodium diet resulted in a significant blood pressure reduction. Reisen et al. (25) reported that hypertensive individuals placed on diets designed to cause weight loss, but without sodium restriction, resulted in a substantial reduction in blood pressure. Tuck et al. (28) reported that weight loss decreased blood pressure in individual who received either a 40 mmol/d sodium diet or a 120 mmol/d sodium diet. Maxwell et al. (22) reported that in obese subjects, weight loss resulted in the same blood pressure reduction whether sodium intake was restricted to 40 mmol/d

of sodium or maintained at 240 mmol/d. Gillum and coworkers (23) found that weight loss without significantly altered sodium intake resulted in blood pressure decreases. Rocchini et al. (29) demonstrated that prior to weight loss, the blood pressure of a group of obese adolescents was very sensitive to dietary sodium intake; however, after weight loss, the obese adolescents lost their blood pressure sensitivity to sodium. Finally, several large clinical trials have also documented that weight loss independent of sodium restriction results in blood pressure lowering. The Hypertension Prevention Trial (19) documented that in individuals with borderline elevations in blood pressure a mean weight loss of 5 kg was associated with as much as a 5/3 mm Hg decrease in blood pressure. The TAIM study (18) also found a significant blood pressure lowering effect of weight loss.

A limitation with the use of studies documenting that weight loss is associated with a reduction in blood pressure is that most studies do not address the long-term effect of weight change on blood pressure in subjects who are again placed on unrestricted diets. Dornfield and coworkers (30) have clearly documented that the long-term changes in blood pressure correlate with changes in body weight. In obese subjects whose blood pressure fell during a very low calorie, protein-supplemented fast, when weight loss stopped and body weight was maintained for 1 month, blood pressure did not increase. In compliant patients who regained <15 lb, 6 months after discontinuation of the very low calorie protein-supplemented fast, blood pressure increased minimally. Similarly, in another group of individuals, who were studied 21 months after being on unrestricted calorie and sodium intake but at a different body weight, Dornfield and associates also documented that differences in blood pressure correlated with differences in body weight. Reisen and Frohlich (31) reported that blood pressure remained reduced in individuals who maintained weight loss for 12–18 months. Finally, Davis et al. (20) reported that weight loss is an effective long-term therapy for maintaining blood pressure in the normal range when it is used as monotherapy or in combination with either thiazide diuretics or  $\beta$ -blockers. Thus, based on all of these weight loss studies, calorie restriction and weight loss are associated with a reduction in blood pressure. In addition, it is clear that even modest weight loss (i.e., 10% of body weight) improves blood pressure, and many individuals achieve normal blood pressure levels without attaining their calculated ideal weight.

However, recent data suggest that long-term weight loss does not reduce the incidence of hypertension. Sjostrom et al. (32) compared the incidence of hyper-

tension and diabetes in 346 patients undergoing gastric surgery with 346 obese control subjects who were matched on 18 variables. After 8 years, the surgical group had maintained a 16% weight loss, whereas the control subjects had a 1% weight gain. These investigators demonstrated that the weight reduction in the surgical group had a dramatic effect on the 8-year incidence of diabetes, but had no effect on the 8-year incidence of hypertension. They (33) and others (34) previously documented that surgical weight loss positively affected blood pressure at 2 and 4 years of follow-up, but that this effect on blood pressure is lost after 8 years of follow-up. These authors have speculated that the “remaining obesity in the surgically treated patients could have induced a reappearance of hypertension during the course of the study independent on ongoing weight increase.” Therefore, Sjostrom’s study suggests that the relapse of blood pressure after surgically induced weight loss is more related to aging and recent small weight increase than to either initial weight or initial weight losses (35).

#### **D Effect of Body Fat Distribution on Blood Pressure**

The definition of obesity also contributes to the controversy regarding the independence of obesity as an etiological determinant of hypertension. Obesity is defined not just as an increase in body weight but rather as an increase in adipose tissue mass. Adipose tissue mass can be estimated by multiple techniques such as: skinfold thickness, body mass index ( $[\text{weight in kg}] / [\text{height in meters}]^2$ ), hydrostatic weighing, bioelectrical impedance, and water dilution methods. In most clinical studies, body mass index is usually used as the index of adiposity. Obesity is generally defined as a body mass index  $>30 \text{ kg/m}^2$ . In 1956, Jean Vague (36) reported that the cardiovascular and metabolic consequences of obesity were greatest in individuals whose fat distribution pattern favored the upper-body segments. Since that observation, several population-based studies have demonstrated that upper-body obesity is a more important cardiovascular risk factor than body mass index alone (37–43). The Normative Aging Study (37) has demonstrated that there is a significant relationship between abdominal circumference and diastolic blood pressure. In fact, the risk of developing hypertension was better predicted by upper body fat distribution than by either body weight or body mass index (Fig. 3). In the Bogalusa Heart Study (38), blood pressure correlated strongly with upper-body fat pattern, but not with measures of global obesity. Many investigators have

**Figure 3** Relationship between diastolic blood pressure (DBP) and abdominal circumference by quintile. With increasing abdominal girth, diastolic blood pressure increases. DBP is shown with 95% confidence intervals for 1972 subjects in the Normative Aging Study. (Adapted from Ref. 37.)

demonstrated that the association of obesity to increased cardiovascular risk is primarily related to upper-body adiposity (44,45). Therefore, since most published studies investigating the role of obesity in hypertension have used total body weight or body mass index, the true role of adiposity in blood pressure regulation may have been obscured.

#### **E Prevalence of Hypertension in Different Obese Populations**

The final proof that obesity is an independent risk factor for hypertension, rather than a chance coexistence of two common clinical disorders, is that the prevalence of hypertension in obese individuals is much higher than in the general population. This increased prevalence of hypertension in obese individuals is even observed in populations with both a high (African-Americans) (2) and low (Mexican-Americans) (46) incidence of hypertension.

### **IV MECHANISM WHEREBY OBESITY MIGHT CAUSE HYPERTENSION**

The exact mechanism whereby obesity causes hypertension is still unknown. Obesity hypertension is complex and multifactorial. It appears to involve insulin resistance, activation of the sympathetic nervous system, activation of the renin angiotensin system, abnor-

mal renal sodium handling, possible leptin resistance, altered vascular reactivity, and alterations in the hypothalamic-pituitary-adrenal axis.

#### **A Insulin Resistance**

For years it has been recognized that hypertension is common in both obese and diabetic individuals. Glucose intolerance, independent of obesity is also associated with hypertension (47). Analysis of data from the San Antonio Heart Study has demonstrated an impressive pattern of overlap among hypertension, diabetes, and obesity. It has been estimated that by the fifth decade of life 85% of diabetic individuals are hypertensive and obese, 80% of obese subjects have abnormal glucose tolerance and are hypertensive, and 67% of hypertensive subjects are both diabetic and obese (7,46). In 1985, Modan et al. (47) demonstrated in a large epidemiological study that a strong association exists among obesity, glucose intolerance, and hypertension. There have been a number of studies in both obese and non-obese humans that demonstrate a strong relationship between insulin resistance and blood pressure (17,47–58). The relationship between insulin resistance and blood pressure has been observed in most populations (55–58). Preliminary results from the Insulin Resistance Atherosclerosis Study (59,60) suggest that after multivariate analysis, insulin resistance and body mass index, but not insulin level, predict hypertension. Therefore, insulin resistance has been suggested by many investigators to be the metabolic link that connects obesity to hypertension.

In support of the hypothesis that hyperinsulinemia may be causally linked to obesity hypertension, it has been demonstrated that in hypertensive obese subjects a 10-hr somatostatin infusion, a hormone that suppress pancreatic insulin release, causes a reduction in both plasma insulin and arterial pressure (61). Somatostatin has also been demonstrated to improve the hyperinsulinemia, hypertension, and dyslipemia associated with fructose-induced hypertension in the rat (62).

Factors known to improve insulin resistance are also associated with reductions in blood pressure. Weight loss has been documented to be associated with both a decrease in blood pressure and an improvement in insulin sensitivity (49,50). The decline in blood pressure associated with exercise training programs seems to be limited to individuals who are initially hyperinsulinemic and have the greatest fall in plasma insulin level as a result of the training program (50,63).

In addition to human data linking insulin and blood pressure, there are also animal data that suggest that

insulin is an important regulator of blood pressure. Rocchini et al. (14,15) demonstrated that the weight gain associated with feeding dogs cooked beef fat is directly associated with an increase in blood pressure and insulin. Reaven and coworkers (64–67) demonstrated that normal Sprague-Dawley rats fed a fructose-enriched diet develop insulin resistance and hypertension. They have shown that the hypertension can be eliminated or attenuated by correcting the insulin resistance either with exercise training or the administration of somatostatin. Kurtz et al. (68) has shown that the genetically obese, insulin-resistant Zucker rat has an increased blood pressure compared to the genetically lean, non-insulin-resistant Zucker rat or Lewis rat. Several investigators have demonstrated that insulin resistance and hyperinsulinemia are also seen in spontaneously hypertensive rats (69–71). In addition, insulin-stimulated glucose uptake is lower in adipocytes isolated from these animals (70). Finally, Brands et al. (72) and Meehan et al. (73) have demonstrated that the infusion of insulin into normal rats results in the development of hypertension. In both studies, a rise in arterial pressure occurred within 2 days of starting the insulin infusion.

Finally, there is evidence to suggest that in normal-weight individuals, hyperinsulinemia and insulin resistance precede the development of hypertension. Young black males with borderline high blood pressure have been reported to have higher insulin levels and more insulin resistance than normotensive black men (55,56). In the Tecumseh Study (74), individuals with borderline hypertension had higher plasma insulin levels and greater weight than normotensive individuals. Normotensive children with a family history of hypertension have higher insulin levels and more insulin resistance than children with no family history of hypertension (75).

However, in contrast to these and other reports (7,47–58), linking hyperinsulinemia to hypertension, there have been studies that have been unable to establish a relationship between hyperinsulinemia and high blood pressure. There is at least one study in a group of hypertensive obese individuals (76) that did not find a correlation between hyperinsulinemia and hypertension. In normal dogs, a chronic infusion of insulin, with or without an infusion of norepinephrine, failed to increase blood pressure (21,77). In addition, even in those reports that have documented a relationship between insulin and blood pressure, there is significant overlap in insulin resistance between those individuals who are hypertensive and those who are normotensive. For example, Pollare and coworkers (49) demonstrated

a significant linear relationship between insulin resistance, measured during a euglycemic insulin clamp study, and blood pressure in a group of 143 hypertensive and 51 normotensive subjects; however, ~50% of the hypertensive subjects had insulin-mediated glucose uptake values that were within 1 standard deviation of the normotensive group (that is, at least one half of the hypertensive subject were not insulin resistant). No correlation has been found between blood pressure and plasma insulin or insulin sensitivity in Pima Indians (78) or obese Mexican-American women (44). Thus, from all of these studies it is clear that not all hypertensive subjects are insulin resistant and that not all insulin-resistant subjects are hypertensive.

Based on available data in the literature, it appears that selective insulin resistance, not just hyperinsulinemia, is more likely the metabolic link that is responsible for the observed epidemiological relationship between obesity and hypertension. The term selective insulin resistance implies that although an individual or animal may have an impaired ability of insulin to cause whole body glucose uptake, some of the other physiological actions of insulin may be preserved. With respect to hypertension, one of the potentially important actions of insulin is the ability to induce renal sodium retention. Obese adolescents have selective insulin resistance in that they are resistant with respect to insulin's ability to stimulate glucose uptake yet are still sensitive to the renal sodium-retaining effects of insulin (79) (Fig. 4). The spontaneously hypertensive rat has also been documented to have impaired insulin mediated whole-rat glucose uptake yet normal insulin sensitivity to induce renal sodium retention (71). In nonobese essential hypertensives, insulin resistance has been demonstrated to involve glucose metabolism but not lipid or potassium metabolism, and is limited to the nonoxidative pathways of intracellular glucose disposal (48,80).

Thus there is evidence to indicate that in obese hypertensive subjects, insulin resistance is *selective* (mostly involving glucose metabolism), *tissue specific* (predominantly effecting skeletal muscle), and *pathway specific* (insofar as only glycogen synthesis is usually affected). Therefore, in any individual or animal the degree to which insulin resistance is tissue and/or pathway specificity may determine whether hypertension will develop. In addition to sodium retention, selective insulin resistance may modulate the development of hypertension through changes in vascular structure and function, alterations in cation flux, activation of the renin angiotensin aldosterone system, and activation of the sympathetic nervous system.

**Figure 4** Panel A depicts the change in glucose uptake (M) (mg/kg/min) during euglycemic hyperinsulinemia in seven obese and five nonobese subjects. Compared to the nonobese individuals, a 40 munit/m<sup>2</sup>/min infusion of insulin resulted in a significant depression in whole-body glucose uptake in the obese subjects ( $P < .001$ ). The plasma insulin response to the insulin infusion was not significantly different between obese and nonobese subjects. Panel B depicts the percent change in urinary sodium excretion (% change UNaV) that occurred in the same seven obese and five nonobese subjects during water diuresis and euglycemic hyperinsulinemia. Insulin infusion resulted in a significant (~50%) decrease in urinary sodium excretion in both the obese and nonobese subjects. There was no significant difference in the response of urinary sodium excretion to hyperinsulinemia observed between the two groups. (From Ref. 79.)

## B Enhanced Sodium Retention

There are ample human and animal data linking obesity hypertension to fluid retention. Rocchini et al. (29) demonstrated that when compared to nonobese adolescents, the obese adolescents have a renal-function relation (plot of urinary sodium excretion as a function of arterial pressure) that has shallower slope. The renal-function relationship is also normalized by weight loss (Fig. 5). The relationship between urinary sodium excretion and mean arterial pressure can be altered by intrinsic and extrinsic factors that are known to affect the ability of the kidney to excrete sodium. Factors that produce alterations in the renal-function curves are constriction of the renal arteries and arterioles, changes

in glomerular filtration coefficients, changes in the rate of tubular reabsorption, reduced renal mass, and changing levels of renin-angiotensin activation, aldosterone, vasopressin, insulin, sympathetic nervous system activation, and atrial natriuretic hormone.

Insulin resistance and/or hyperinsulinemia can result in chronic sodium retention. Insulin can enhance renal sodium retention both directly, through its effects on renal tubules (79,81,82), and indirectly, through stimulation of the sympathetic nervous system and augmenting angiotensin II mediated aldosterone secretion (83,84). There are data to suggest that insulin resistance is directly related to sodium sensitivity in both obese and nonobese subjects. Rocchini et al. (29) have also shown in obese adolescents that insulin resistance and sodium sensitivity of blood pressure are directly related. They demonstrated that the blood pressure of obese adolescents is more dependent on dietary sodium intake than the blood pressure of nonobese adolescents and that hyperinsulinemia and increased sympathetic nervous system activity appear to be responsible for the observed sodium sensitivity and hypertension. Finta et al. (85) demonstrated that the endogenous hyperinsulinemia that occurs in obese subjects following a glucose meal

**Figure 5** Renal-function relations for 18 nonobese (X), 60 obese adolescents before a weight loss program (open square) and the 36 obese adolescents who lost weight during a 20-week weight loss program (closed square). In comparison with the nonobese adolescents' renal-function relation, the obese adolescents' renal-function relation has a shallow slope ( $P < .001$ ). In those who lost weight, the slope increased (arrow). This increase was due to a decrease in the mean arterial pressure during the two weeks of the high salt diet. (From Ref. 29.)

can result in urinary sodium retention. In that study, the investigators also demonstrated that the obese adolescents who were the most sodium sensitive had significantly higher fasting insulin concentrations, higher glucose-stimulated insulin levels, and greater urine sodium retention in response to the oral glucose load. Finally, in nonobese subjects with (82) or without (86) essential hypertension there is a direct relationship between sodium sensitivity and insulin resistance.

There are also animal data that suggest that insulin resistance may be in partly responsible for the sodium retention associated with obesity hypertension. In a dog model of obesity induced hypertension, Rocchini et al. (14,15) demonstrated that during the first week of the high-fat diet, the increase in sodium retention appeared to best relate to an increase in plasma norepinephrine activity, whereas during the latter weeks of the high-fat diet, an increase in plasma insulin appeared to be the best predictor of sodium retention. Finally, Rocchini et al. (86) demonstrated that the hypertension associated with weight gain in the dog occurs only if adequate salt is present in the diet.

In non-insulin-resistant subjects, both a concomitant decrease in proximal tubular sodium reabsorption and an increase in glomerular filtration oppose the direct effect of insulin to increase distal sodium retention (87). Hall and coworkers (88) have demonstrated that obesity-induced hypertension in the dog is associated with increased renal tubular sodium reabsorption since marked sodium retention occurred despite large increases in glomerular filtration and renal plasma flow. Ter Maaten et al. (89) have demonstrated that insulin-mediated glucose uptake was positively correlated with changes in glomerular filtration but not with changes in either proximal tubular sodium reabsorption or overall fractional sodium excretion. They speculated that insulin could only cause abnormal sodium retention if an additional antinatriuretic stimulus is present, such as through stimulation of the sympathetic activity, augmenting angiotensin II-mediated aldosterone production, and others.

Another mechanism that may link insulin and insulin resistance to salt-sensitive hypertension is alterations in insulin receptor structure or function. We characterized the change in insulin-mediated glucose uptake that occurs with feeding dogs a high-fat diet by measuring insulin-mediated glucose uptake dose response curves in dogs before and after 1, 3, and 6 weeks of the high-fat diet (90) (Fig. 6). After 1 week of the high-fat diet there was a significant increase in the amount of insulin that was required to produce a half-maximal response in glucose uptake (insulin  $ED_{50}$  dose) and little change in

**Figure 6** Rates of whole-body glucose uptake ( $M$ ) determined during euglycemic clamp studies over a wide range of steady-state insulin concentrations serially in four dogs fed a high-fat diet. Weight gain resulted in a shift to right and a decrease in maximal rate of  $M$ .  $P < .001$ . (From Ref. 90.)

the maximal glucose uptake response. However, by 3 weeks of the high-fat diet there was a further increase in the insulin  $ED_{50}$  dose and a significant reduction in the maximal insulin-induced glucose uptake. Laasko et al. (91) reported, in obese humans, similar changes in the insulin mediated glucose uptake dose response relationship. Kolterman et al. (92) suggested that insulin resistance in obesity is due to target tissue defects (i.e., reduced sensitivity to insulin, reduced responsiveness to insulin, or a combined defect). Reduced sensitivity to insulin is believed to be due to a prereceptor or receptor defect. In this type of resistance, high concentrations of insulin overcome the defect and evoke a maximum insulin stimulation of the tissue. Alternatively, reduced responsiveness to insulin is associated with a reduced maximum insulin stimulation of the tissue, and is believed to be due to a defect that is distal to the insulin-receptor complex. Since weight gain is associated with both a reduced maximum insulin-stimulated glucose uptake and a shift of the dose response curve to the right (i.e., a significantly reduced insulin  $ED_{50}$  dose), using Kolterman's terminology, weight gain in the dog results in both a reduced sensitivity and responsiveness to insulin. We also observed that  $> 77\%$  of the variance

in the weekly change in blood pressure and sodium retention caused by feeding dogs a high-fat diet could be explained by the weekly insulin-stimulated glucose uptake insulin ED<sub>50</sub> doses. Therefore, insulin resistance appears to be important in producing the salt-sensitive hypertension observed in obese humans and dogs. Sechi (93) reported that dietary salt content can alter insulin receptor function in the SHR rat and the fructose-fed rat. An increase in dietary salt content decreases insulin receptor number and mRNA levels only in the kidney of WKY but not SHR. Similarly, Sechi reported that when control Sprague-Dawley rats are fed a high-salt diet, renal insulin receptor number and mRNA levels decrease. However, when fructose is added to the high-salt diet, renal insulin receptor number and mRNA levels did not decrease. Therefore, Sechi has speculated that in both SHR and fructose-fed rats, the sensitivity to insulin of the kidney is unresponsive to manipulations of dietary sodium. He believes that this abnormality might contribute to sodium retention and hypertension.

Finally, there are structural changes in the kidneys of obese individuals that can cause fluid retention. The kidneys from obese animals and humans are tightly encapsulated with fat tissue. Some of the fat penetrates the renal hilum into the sinuses surrounding the renal medulla (94). The interstitial fluid hydrostatic pressure is elevated to 19 mm Hg in obese dogs, compared with on 9–10 mm Hg in lean dogs. The elevated interstitial pressure reduces medullary blood flow and causes tubular compression, thus slowing tubular flow rate and increasing fraction tubular reabsorption. Therefore, obesity, either from hormonal changes or due to physical changes in the kidney, causes fluid retention.

### C Alterations in Vascular Structure and Function

Another way that obesity can cause hypertension is through alterations in vascular structure and function. Cellular metabolism of cations and other molecules may be altered in obesity and lead to changes in vascular responsiveness. Since insulin and insulinlike growth factors are mitogens capable of stimulating smooth muscle proliferation (95), hyperinsulinemia could result in vascular smooth muscle hypertrophy, narrowing of the lumen of resistance vessels, and ultimately the development of hypertension (96). Vascular abnormalities are also known to exist in obese individuals. In normal nonobese volunteers, insulin induces peripheral arterial vasodilation (97). In obese adolescents, Rocchini et al. (98) demonstrated that ischemic exercise results in a decreased maximal forearm blood flow and an increased

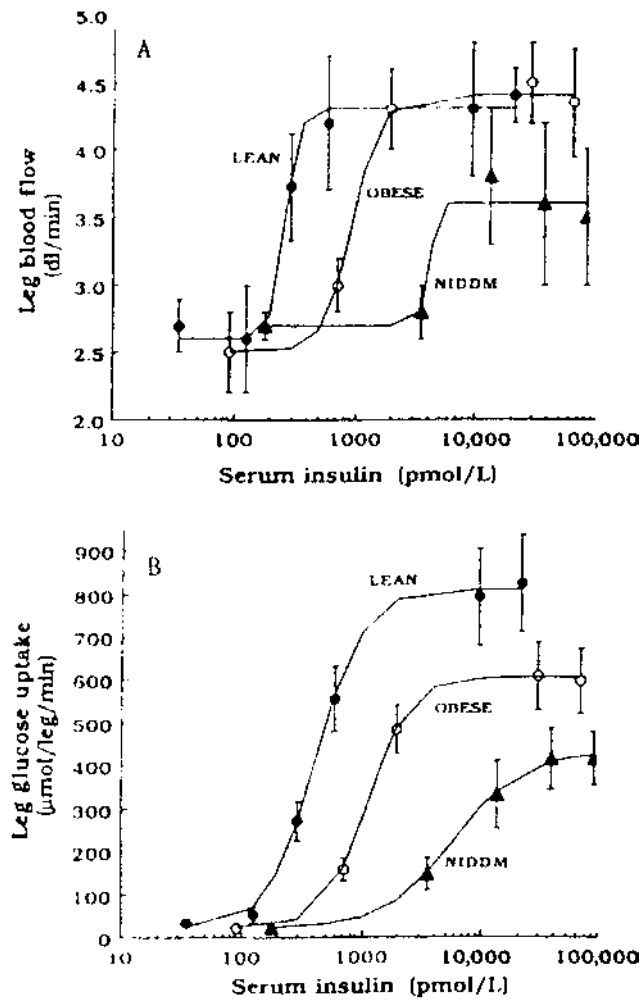

minimum vascular resistance. These investigators demonstrated that the abnormal vascular responses to ischemic exercise directly correlate with fasting insulin and whole-body glucose uptake, and that the vascular and metabolic abnormalities improve with weight loss.

In the dog, euglycemic hyperinsulinemia increases cardiac output in a dose-dependent fashion (90). However, feeding the high-fat diet resulted in right shift of insulin's effect to increase cardiac output. Compared to the control fed dogs, the half-maximal response in the insulin-induced increase in cardiac output (insulin ED<sub>50</sub> dose) was 72% ( $P < .05$ ) higher at 1 week and 180% ( $P < .01$ ) higher at 6 weeks. Similarly, weight gain in the dog blunts the vasodilator response to insulin in the femoral artery. Steinberg et al. (99) demonstrated that insulin enhances the release of endothelium-derived nitric oxide. Baron et al. (100) demonstrated that insulin-resistant individuals exhibit blunted insulin-mediated vasodilatation and impaired endothelium-dependent vasodilatation. Others have also demonstrated that salt-sensitive and insulin-resistant hypertensive patients manifest impaired endothelium-dependent relaxation mediated by nitric oxide (101,102).

In addition to insulin resistance possibly being associated with the development of vascular changes, there also are data that suggest that abnormalities in skeletal muscle vascular regulation may be a cause of insulin resistance. In both the dog (97) and man (97) euglycemic hyperinsulinemia has been documented to result in vasodilatation, not vasoconstriction. Even though the exact mechanism how insulin induces vasodilatation in non-insulin-resistant individuals is unknown, some investigators believe that this vasodilator response is in part due to stimulation of endothelial-dependent relaxing factor (103,104). Type 2, but not type 1, diabetic subjects respond abnormally to acetylcholine, which induces vasodilatation by stimulation of endothelial-dependent relaxing factor (105).

Insulin-mediated glucose uptake is determined both by insulin's ability to stimulate glucose extraction at the level of tissues/cells and by the rate of glucose and insulin delivery (blood flow). Thus, the relative contributions of tissue and blood flow actions of insulin will determine the overall rate of glucose uptake (i.e., degree of insulin resistance). In obese individuals with insulin resistance, an attenuated limb vasodilator responses to hyperinsulinemia has been reported (106,107) (Fig. 7). The lack of insulin's ability to produce vasodilatation has led Baron (108) to speculate that abnormalities of skeletal muscle vascular regulation may be a cause, not a result, of insulin resistance. This hypothesis is also

**Figure 7** Rates of leg blood flow (A) and rates of leg glucose uptake (B) determined during euglycemic clamp studies over a wide range of steady-state serum insulin concentrations in lean (closed circles) and obese nondiabetic subjects (open circles) and patients with NIDDM (close triangles). Note the log scale on the abscissa. To convert the insulin concentrations from pmol/L divide by 7.175. (Adapted from Ref. 90.)

supported by the fact that antihypertensive drugs that are vasodilators (i.e., captopril, calcium channel blockers, and prazosin) tend to improve insulin resistance, whereas other antihypertensive drugs such as diuretic or beta-blockers do not (109–111).

Skeletal muscle characteristics are altered in obesity (112–115) and hypertension (116–119), and these alterations may be involved in the etiology of these two diseases. Human muscle has three categories of fiber: types I, IIa, and IIb (120). Type I fibers have high aerobic capabilities and increase capillarization. Type

II fibers tend to be better suited for anaerobic metabolism. Type IIa fibers have the same capillary supply as type I fibers, whereas type IIb fibers have a reduced capillary supply. Lithell et al. (113) reported that muscle fiber diameter and capillary density correlate with fasting insulin levels. These investigators also demonstrated that obese men have an increased fiber diameter with no increase in the number of capillaries per fiber (i.e., a reduced capillary density). Lillioja et al. (112) reported similar results in a group of Pima Indians. Wade et al. (105) and Staron et al. (114) reported a significant inverse correlation between the presence of type I fibers and body fatness. However, Simoneau and Bouchard (121) found no relationship between percent body fat and the percentage of type I fibers in a group of 126 women and 213 men. The only significant correlation between body fatness and fiber type observed in this study was that obese men appeared to have an increase percentage of type IIb fibers with low aerobic enzyme activities. Krotkiewski and Bjorntrop (122) observed that upper-body obesity, increased waist-to-hip ratio, was associated with an increased percentage of type II fibers. Based on these observations, it has been speculated that the hypertension and insulin resistance observed in some obese individuals, especially those with upper-body obesity, may be due to the high percentage of type IIb muscle fibers that have low capillary density and reduced aerobic enzyme activities. In support of this theory is the observation that endurance training in obese and nonobese individuals improves insulin resistance by increasing muscle oxidative capacity and increasing capillary density (123,124).

#### D Alterations in Ion Transport

The fourth method by which obesity could cause hypertension is through alterations in cation transport. Insulin has been shown to affect sodium and calcium transport, although controversy still exists regarding the molecular mechanism of this effect. A direct effect of insulin on sodium/hydrogen exchange has been demonstrated in vitro (125). Insulin has been reported to both increase and decrease Na-K-ATPase activity (126). Insulin has been linked to both Na-Li countertransport and Na-K cotransport (126). In a study of leukocyte sodium content and sodium pump activity in overweight and lean hypertensive subjects, it was observed that overweight hypertensive subjects accumulated intracellular sodium probable through abnormalities of sodium pump activity (127). In obese hypertensive men, the renin-angiotensin system and sympathetic nervous system activity are reported to influence the

regulation of erythrocyte sodium turnover during sodium and energy restriction (128). Thus, alteration in intracellular sodium concentration could lead to an increased intracellular calcium, an increase in vascular smooth muscle tone, and hypertension. Insulin alone has also been demonstrated to elevate cytosolic free calcium levels in adipocytes of normal subjects (129). In addition, weight loss in obese individuals is reported to be accompanied by a significant decrease in platelet-free calcium levels (130).

Insulin-mediated glucose transport is dependent on an intracellular calcium concentration of between 40 and 375 nm/L (131). Thus, increased intracellular calcium concentration might lead to insulin resistance, increased vascular resistance, and hypertension (50). In hypertensive type II diabetics a decrease in calcium adenosine-triphosphate activity is associated with increased intracellular calcium concentration (132). Insulin has also been shown to stimulate plasma membrane calcium adenosine-triphosphate activity (105) and sodium-potassium adenosine-triphosphate activity (126). Insulin resistance may blunt these pump functions and could lead to chronic increases in intracellular calcium, increased peripheral vascular resistance, and hypertension. Finally, reduced intracellular levels of magnesium are also associated with increased vascular resistance and insulin resistance (133). With the use of magnetic resonance imaging to evaluate the aorta of normal and hypertensive subjects, Resnick et al. (134) found that increased abdominal visceral fat, decreased intracellular magnesium, and advanced age were closely associated with reduced aortic distensibility vessels. Therefore, in obesity, alterations in either intracellular calcium and/or magnesium could result in the development of both hypertension and insulin resistance.

### **E Stimulation of the Renin-Angiotensin-Aldosterone System**

A fifth way by which obesity could cause hypertension is through alterations in the renin-angiotensin-aldosterone system. The renin-angiotensin-aldosterone system is an important determinant of efferent glomerular arteriolar tone and tubular sodium reabsorption. Its activity is modulated by both dietary salt ingestion and blood pressure. Therefore alterations in the renin-angiotensin-aldosterone system could be expected to alter pressure natriuresis. Enhanced activity of the renin-angiotensin system has been reported in obese humans and dogs (28,84,135–140). Tuck et al. (28) demonstrated in obese hypertensives that with weight loss plasma renin activity decreases and that the decrease in plasma renin

activity was statistically correlated with the weight loss-associated decrease in mean arterial pressure. Granger and coworkers (140) reported that plasma renin activity is 170% higher in obese dogs than in control dogs. However, Hall et al. (88) demonstrated that weight-related changes in blood pressure can occur in dogs independent of changes in angiotensin II.

Obesity is also associated with abnormalities in the angiotensin-aldosterone system. In the dog, Rocchini et al. (14,15) demonstrated that the increase in blood pressure associated with weight gain is directly related to sodium retention and that this sodium retention is in part accompanied by an increase in plasma norepinephrine, insulin, and aldosterone concentrations. Tuck and associates (28) demonstrated in obese adults that weight loss lowered both plasma renin activity and aldosterone concentration. Hiramatsu et al. (136) documented in obese hypertensives that with increasing body weight, there is a progressive increase in the ratio of plasma aldosterone to plasma renin activity. Scavo et al. (137,138) reported that although obese adults have a normal plasma renin activity, they have an increased plasma aldosterone concentration and an increased aldosterone secretion rate. Sparks and coworkers (139) reported that in obese patients during the early stages of fasting there is a dissociation between plasma renin activity and aldosterone. Rocchini et al. (135) measured supine and 2-hr upright plasma renin activity and aldosterone in 10 nonobese and 30 obese adolescents before and after a 20-week weight loss program. The obese adolescents had significantly higher supine and 2-hr upright aldosterone concentrations. Although plasma renin activity was not significantly different in the two groups of adolescents, they observed that a given increment in plasma renin activity produced a greater increment in aldosterone in the obese adolescents. Compared with an obese control group, weight loss resulted in a significant decrease in plasma aldosterone. After weight loss there was also a significant decrease in the slope of the posture-induced relation between plasma renin activity and aldosterone. In addition, after weight loss there was a significant correlation between the change in plasma aldosterone and the change in mean blood pressure. The authors speculated that increased plasma aldosterone concentration in some obese subjects is caused by increased adrenal sensitivity to angiotensin II.

Insulin has been shown to influence the renin-angiotensin-aldosterone system in both normal subjects (83,141) and in patients with diabetes (142). Since hyperinsulinemia is a characteristic feature of obesity, Rocchini et al. (84) hypothesized that increased aldosterone

terone levels observed in obese individuals are caused by hyperinsulinemia and insulin's ability to augment angiotensin II-mediated aldosterone production. Rocchini et al. (84) measured the increase in plasma aldosterone after intravenous angiotensin II (5, 10, and 20 ng/kg/min for 15 min each) before and after euglycemic hyperinsulinemia in seven chronically instrumented dogs. Euglycemic hyperinsulinemia (at insulin doses of 2, 4, or 8 mU/kg/min) resulted in a significantly greater ( $P < .01$ ) change in the angiotensin II-stimulated increments of plasma aldosterone than was observed when angiotensin II was administered alone. However, there was no dose dependence of insulin's effect on angiotensin II-stimulated aldosterone. The effect of weight gain on the angiotensin II response was also evaluated in five dogs. Weight gain significantly increased angiotensin II-stimulated aldosterone; however, with hyperinsulinemia, the response was not significantly different than that observed in the dogs prior to weight gain. The authors speculated that possible mechanisms whereby insulin could increase angiotensin II-stimulated aldosterone production include increased intracellular potassium, reduced plasma free fatty acids, and a direct action of insulin to induce increased adrenal steroidogenesis.

Hollenberg and Williams (143,144) have described a group of subjects with essential hypertension that they have called nonmodulators. These normal renin subjects appear to have a defect in their sodium-modulated tissue responsiveness to angiotensin II. Ferri et al. (145) have shown that nonmodulating hypertensives are insulin resistant. Similarly, Trevisan et al. (146) has demonstrated that IDDM patients have both an enhanced renal response to angiotensin II and insulin resistance.

## **F Increased Activation of the Sympathetic Nervous System**

The sixth way by which obesity could cause hypertension is through stimulation of the sympathetic nervous system. For over 20 years it has been recognized that diet affects the sympathetic nervous system. Fasting suppresses sympathetic nervous system activity, whereas overfeeding with either a high-carbohydrate or high-fat diet stimulates the sympathetic nervous system (147–150). Insulin is believed to be the signal that networks dietary intake and nutritional status to sympathetic activity. Glucose and insulin sensitive neurons in the ventromedial portion of the hypothalamus have been demonstrated to alter the activity of inhibitory pathways between the hypothalamus and brainstem (151). It is believed that the physiological role of

the link between dietary intake and sympathetic nervous system activity is to regulate energy expenditure in a hope to maintain weight homeostasis. Landsberg and Krieger (152) have suggested that in obese individuals the sympathetic nervous system is chronically activated in an attempt to prevent further weight gain and that hypertension is a byproduct of the overactive sympathetic nervous system. They and their associates, as have others, have clearly documented that euglycemic hyperinsulinemia in both normal and obese humans and animals causes activation of the sympathetic nervous system as documented by increases in heart rate, blood pressure, and plasma norepinephrine (26,84,152–155).

More recently it has been shown that hyperinsulinemia in normal humans is associated not only with an increase in circulating catecholamines but also with an increase in sympathetic nerve activity (97). Fisher rats fed a high-fat diet develop obesity, hypertension, and insulin resistance. When euglycemic insulin infusions are performed, increases in systolic blood pressure are observed in the fat-feed animals but not in controls. The blood pressure increase is reversible by combined  $\alpha$ -blockade and  $\beta$ -blockade, thus suggesting a role for increased sympathetic activity (156). Hall et al. (157) have preliminary studies suggesting that combined alpha and beta adrenergic blockade for 7 days reduced arterial pressure to a much greater extent in obese than in normal dogs. These investigators have also demonstrated that renal denervation prevents both the hypertension and sodium retention associated with obesity in the dog (158).

Although many studies in obese individuals have demonstrated increased sympathetic nervous system activity, this has not been a universal finding (159). Part of the controversy regarding the role of the sympathetic nervous system in obesity relates to relying on plasma levels of catecholamines as the index of sympathetic activity. Recent data from the Normative Aging Study (37) strongly suggest that obesity is associated with increased sympathetic nervous system activity. This study demonstrated that sympathetic activity, assessed by measuring 24-hr urinary norepinephrine excretion, is directly related to abdominal girth, waist-to-hip ratio, and body mass index. In addition, norepinephrine excretion is directly correlated with both glucose level and fasting insulin concentration (37,160). Other recent studies using the appearance rate of norepinephrine in the circulation (161) and the effects of somatostatin-induced suppression of insulin on plasma norepinephrine levels (162) provide additional corroborative data for an increase in sympathetic activity linked to obesity and driven by insulin. Sondergaard et al. (163) demon-

strated that measurements of resting and 24-hr sympathoadrenal activity may differ in obese individuals. They demonstrated that sympathetic activity at rest as evaluated by forearm venous plasma norepinephrine levels was increased in obese subjects. However, thrombocyte norepinephrine and epinephrine levels, which likely reflect 24-hr plasma catecholamine concentrates, were reduced in obese subjects with a body fat percentage above 40%. They speculate that the reduced thrombocyte catecholamine levels are probable due to a reduced physical activity in these subjects.

Finally, there are also ethnic differences in sympathetic tone. Weyer et al. (164) examined the relation among heart rate, blood pressure, percent body fat, fasting insulin, and muscle sympathetic nerve activity in male normotensive whites and Pima Indians. These investigators demonstrated that in both ethnic groups, heart rate and blood pressure positively related to percent body fat and muscle sympathetic nerve activity, and both were independent determinants of heart rate and blood pressure. However, muscle sympathetic nerve activity was positively related to percent body fat and fasting insulin concentration in whites but not in Pima Indians. This study emphasizes that the roles of hyperinsulinemia and increase sympathetic nervous system activity as mediator for the relation between obesity and hypertension can differ between among ethnic groups. Weyer's study (164) may explain why the Pima Indians have a low prevalence of hypertension in this population despite their high incidence of obesity and insulin resistance.

Abnormalities in the sympathetic nervous system may also play role in the actual pathogenesis of some forms of obesity. The recent identification and cloning of the  $\beta_3$ -adrenergic receptor have spurred great interest in the potential role of this receptor in the regulation of energy expenditure and ultimately in the development of obesity. The  $\beta_3$ -adrenergic receptor is predominantly expressed in omental fat tissue and gallbladder, at low levels in ileum and colon, and absent in muscle, heart, liver, lung, kidney, thyroid, and lymphocytes (165). Mutations in the  $\beta_3$ -adrenergic receptor gene have been detected in Pima Indians and Mexican-Americans, two populations with a high incidence of obesity and diabetes (166). Finally, preliminary studies in obese humans have demonstrated that the administration of an agent with high specificity for the  $\beta_3$ -adrenergic receptor results in increased energy expenditure that is accompanied by a marked improvement in insulin sensitivity and glucose tolerance (167).

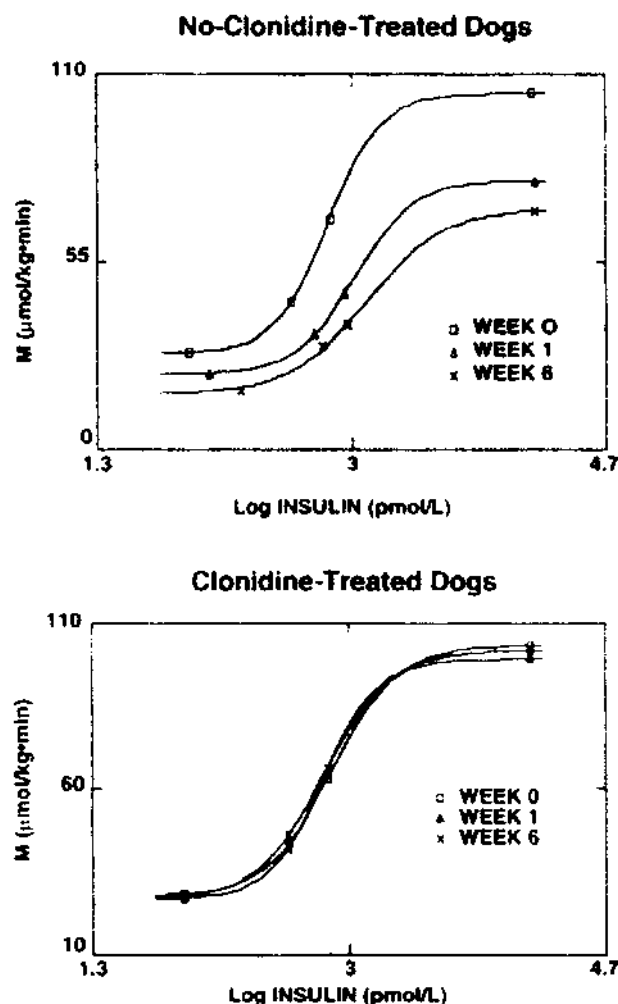

Finally, there is evidence suggesting that alterations in sympathetic activity can cause insulin resistance. The

acute administration of catecholamines is known to decrease insulin action (168). Diebert et al. (169) demonstrated that epinephrine, acting primarily through a beta-adrenergic receptor, markedly impairs both peripheral and hepatic resistance to the action of insulin. Jamerson et al. (170) demonstrated that a reflex increase in sympathetic tone in normotensive individuals can lead to acute insulin resistance in the forearm. These investigators speculated that reflex activation of the sympathetic nervous system caused a decrease in forearm glucose uptake that was mediated through a reduction in blood flow to the forearm. Rosen et al. (171) demonstrated that central activation of imidazoline receptors by moxonidine can prevent both the hypertension and insulin resistance associated with feeding rats a high fructose diet. Similarly, Ernsberger et al. (172) demonstrated that moxonidine completely reversed abnormal glucose tolerance and insulin resistance in obese spontaneously hypertensive rats. Finally, Rocchini et al. (173) have shown that clonidine can prevent the hypertension, sodium retention, and insulin resistance associated with feeding dogs a high-fat diet (Fig. 8). Therefore, it is possible that altered sympathetic function could be the metabolic abnormality that is responsible for obesity hypertension, salt sensitivity, and insulin resistance.

## G Natriuretic Peptides

Natriuretic peptides are important regulators of volume and pressure. There are at least three natriuretic peptides that have been identified: atrial natriuretic peptide, brain natriuretic peptide, and C-type peptide. Few studies have examined the role of natriuretic peptides in obesity. Licata and coworkers (174) demonstrated that following a sodium load, obese subjects have delayed urinary sodium excretion and a blunted rise in atrial natriuretic peptide levels. Maoz and coworkers (175) demonstrated that weight loss was associated with a significant diuresis and natriuresis together with an early increase in plasma atrial natriuretic peptide levels. Finally, Dessi-Fulgheri et al. (176) reported that after caloric restriction in obese hypertensive subjects atrial natriuretic peptide infusion caused a more pronounced diuresis, natriuresis, fall in blood pressure, and an elevation in plasma cGMP levels than was observed in these subjects prior to caloric restriction. These authors suggested that relative over expression of inactive receptor Npr-C in adipose tissue might trap and clear more atrial natriuretic peptide from the circulation and thereby reduce its biologic effects on the kidney.

**Figure 8** Rates of whole-body insulin-mediated glucose uptake ( $M$ ) determined during euglycemic clamp studies over a wide range of steady-state insulin concentrations ( $\square$ , week 0;  $\Delta$ , week 1 of fat diet;  $\times$ , week 6 of fat diet) in dogs fed a high-fat diet with and without clonidine treatment. Weight gain resulted in a shift to the right and a decrease in the maximal rate of  $M$  ( $P < .001$ ) in dogs not treated with clonidine; however, if the dogs were treated with clonidine, weight gain did not alter the dose-response relation. (From Ref. 173.)

## H Leptin

Leptin is a 167-amino acid hormone that is secreted exclusively by adipocytes. By binding to the leptin receptor in the hypothalamus and by activating multiple neuropeptide pathways, leptin decreases appetite and increases energy expenditure, thereby decreasing adipose tissue mass and body weight. Serum leptin level is low in lean individuals and is elevated in most obese

subjects (177). Since there is a strong relation between serum leptin levels and body fat mass, some authors have concluded that obesity may be associated with leptin resistance (178).

Leptin has been shown to have significant cardiovascular effects. Leptin-treated animals have a higher metabolic rate and core temperature. This may be because leptin increases sympathetic outflow and norepinephrine turnover in adipose tissue (179). Despite the increase in sympathetic outflow associated with leptin administration, no blood pressure elevation has been reported with the acute infusion of leptin (180). However, the chronic administration of leptin is associated with an increase in blood pressure, heart rate, and renal vascular resistance despite a decrease in food intake (181). Transgenic mice that overexpress leptin also are hypertensive. In these mice the elevated blood pressure can be prevented by an  $\alpha$ -receptor blocker (182). Leptin has also been found to increase insulin sensitivity and inhibit glucose-mediated insulin secretion (183).

## I Hypothalamic Origins of Obesity Hypertension

The similarities between Cushing's syndrome and the metabolic abnormalities associated with obesity hypertension has lead Bjorntorp to speculate that hypercortisolemia is involved with in the pathogenesis of obesity hypertension (184). Cortisol secretion has been measured repeatedly in obesity, but there have been conflicting results. There is evidence of increased secretion and turnover, resulting in normal or even lower than normal circulating concentration (185). Measuring salivary cortisol, investigators have been able to demonstrate that normally regulated cortisol secretion is associated with "healthy" anthropometric, metabolic, and hemodynamic variables. However, upon perceived stress cortisol secretion is increased and followed by insulin resistance, abdominal obesity, elevated blood pressure, and hyperlipidemia (186,187). In a small portion of the population a defect, "burned-out" cortisol secretion occurs. This "burnout" also is associated with decreased sex steroid and growth hormone secretions and is strongly associated with visceral adiposity, insulin resistance, and hypertension. Rosmond and Bjorntorp (188) have demonstrated that diminished dexamethasone suppression is directly associated with obesity and elevation of leptin levels. These authors suggest that a poor control of the hypothalamic-pituitary axis may be associated with obesity and inefficient leptin signals. Zahrezewska et al. (189) demonstrated in rats that glucocorticoids diminish leptin signals.

Bjorntorp and Rosmond (184) speculate that the two ways that elevated activity of the hypothalamic-pitui-

tary adrenal axis could occur are an elevated stimulation and/or a diminished feedback control. Elevated stimulation of the HPA axis can occur owing to psychosocial and socioeconomic handicaps such as living alone, divorce, poor education, low social class, unemployment, and problems at work when employed, or even excess food intake. (190) With respect to causes of diminished feedback control of the HPA axis, Bjorntorp and others (191–193) have demonstrated that a restriction fragment length polymorphism of the glucocorticoid receptor gene is associated with poorly controlled HPA axis function, as well as abdominal obesity, insulin resistance, and hypertension. Therefore Bjorntorp has suggested that many of the cardiovascular and physiologic consequences found in obese individuals could be due to “a discretely elevated cortisol secretion, discoverable during reactions to perceived stress in everyday life” (194).

## J Summary

In summary, there are conclusive data to suggest the obesity, especially upper-body fat distribution, is an independent risk factor for the development of hypertension. Calorie restriction and weight loss are associated with a reduction in blood pressure. In addition, it is clear that even modest weight loss (i.e., 10% of body weight) improves blood pressure, and many individuals achieve normal blood pressure levels without attaining their calculated ideal weight. Although controversy exists as to the role that insulin resistance and hyperinsulinemia play in the pathogenesis of obesity hypertension, there are ample data suggesting that selective insulin resistance and hypertension are related. Other hormonal systems (leptin, renin-angiotensin-aldosterone, sympathetic nervous system, and hypothalamic-pituitary-adrenal axis) have also been identified to relate to obesity, hypertension, and insulin resistance. Further studies will be necessary not only to clarify the origin of defects in insulin action that are responsible for the development of insulin resistance, but also to more precisely define the exact role that insulin resistance and the regulatory abnormalities in these other hormone systems play in blood pressure homeostasis.

## V OBESITY AS A CARDIOVASCULAR RISK FACTOR

The Framingham Heart Study (4) identified obesity and hypertension as independent risk factors for the development of cardiovascular disease. Obese normotensive

and hypertensive men have a higher rate of coronary heart disease (43). Manson et al. (195) also reported that, in women, the relative risk of fatal and nonfatal coronary heart disease increased from the lowest to the highest quartiles of obesity. However, other large studies (196,197) have reported an attenuated risk of cardiovascular mortality and morbidity among individuals who have both hypertension and obesity. Long-standing obesity is associated with preclinical and clinical left ventricular dilation (198) and impaired systolic function (199,200), with heart failure frequently being the ultimate cause of death in markedly overweight individuals (201).

A physiological change that may contribute to the association of obesity with left ventricular dilation is sodium retention with a concomitant increase in blood volume and cardiac output. Although many investigators (202) have reported that obesity is associated with an increased cardiac output and blood volume, when cardiac output and blood volume are indexed for body surface area, the differences between lean and fat disappear. Since obese and nonobese hypertensive subjects do not differ in their hemodynamic and volume characteristics when normalized for surface area, some investigators (203) have concluded that obesity does not result in a unique alteration in the vascular system that would produce hypertension. However, normalization for surface area may not be appropriate in the obese subject. Since the increment in cardiac output associated with obesity cannot be explained by an increase in adipose tissue perfusion alone, some have suggested that blood flow to the nonadipose mass must also be increased in obese subjects (204,205). Thus, obesity is characterized by a relative volume expansion in the presence of restricted vascular capacity.

Regional changes in organ blood flow and resistance have been studied in the dog (206). After 6 weeks of the high-fat diet, regional flows significantly increased in all measured organ beds, whereas in the control fed dogs, regional flows remained unchanged from baseline values. Weight gain was not associated with a change in vascular resistance in the heart, kidney, or brain but was associated with a significant decrease in gastrointestinal tract resistance. In addition to these data in the dog, there are also human data to suggest that regional hemodynamic abnormalities are present in obesity. Both renal and splanchnic blood flow (204) have been reported to be increased in obese subjects. In the obese adolescent, regional forearm blood flow, measured by venous occlusion plethysmography, is increased, and forearm vascular resistance is decreased (98). Both of these abnormalities are reversed with weight loss. Finally, Schmieder and Messerli (207) assessed systemic

and renal hemodynamics and left ventricular function and structure in a group of 207 individuals. They noted that obese hypertensives had lower total peripheral resistance, a significantly higher stroke volume-pulse pressure index, and an elevated renal vascular resistance. They also noted that the degree of left ventricular hypertrophy was greater in the hypertensive than in the normotensive individuals, and it progressively increased with obesity.

Since obesity is associated with an increased preload to the left ventricle, dilatation and eccentric left ventricular hypertrophy (198,204,208) evolve. Hypertension increases afterload, and as a consequence the left ventricle adapts with an increase in wall thickness. The combination of obesity and hypertension therefore creates a double burden on the heart, ultimately leading to the development of impaired ventricular function (199–201,209,210).

MacMahon et al. (198) reported that 50% of individuals who are > 50% overweight have left ventricular hypertrophy. As with blood pressure, weight loss can result in a regression in the left ventricular hypertrophy (198,208,211). Unlike the universal finding of the left ventricular hypertrophy in obese individuals, not all studies have demonstrated an impairment in left ventricular function. Schneider and Messerli (207) reported that obese hypertensive individuals have normal global left ventricular systolic function as measured by left ventricular fractional shortening and velocity of circumferential fiber shortening. However, since both of these indices of left ventricular systolic function are dependent on ventricular preload and afterload, the results of Schneider's study do not document that left ventricular contractility is normal. In fact, Blake and coworkers (208) demonstrated that despite a normal left ventricular ejection fraction at rest, obese individuals have an impaired left ventricular ejection fraction in response to dynamic exercise. Guillermo et al. (209) reported that the end-systolic wall stress to end-systolic volume index, a load independent index of left ventricular function, is also abnormal in even mildly or moderately obese individuals. These investigators also documented a significant inverse relationship between the index of end-systolic wall stress to end-systolic volume and body mass index, diastolic diameter, and left ventricular mass index.

Abnormalities in left ventricular filling have also been reported to occur in obese individuals, i.e., decreased peak filling rate, duration of peak filling and left atrial emptying index (211), an increased isovolumic relaxation time, and an abnormal mitral valve Doppler filling pattern (210). The left ventricular hypertrophy,

depressed myocardial contractility, and diastolic dysfunction can predispose individuals to excessive ventricular ectopy. Messerli et al. (212) reported that the prevalence of premature ventricular contractions was 30 times higher in obese individuals with eccentric left ventricular hypertrophy than in lean individuals.

The cardiovascular response to stress is thought to relate to cardiovascular risk. Rockstroh and associates (213) demonstrated that obese hypertensive individuals respond abnormally to stress. In their study, they evaluated the hemodynamic responses to mental and isometric stress in obese and nonobese hypertensive individuals. They observed that obese hypertensive individuals responded to mental stress with vasoconstriction and to isometric stress with an exaggerated increase in arterial pressure.

Finally, as with hypertension, insulin resistance may be related to both the cardiac hypertrophy and abnormal cardiac function that is observed in many obese individuals. Nakajima et al. (214) reported that there is a direct relationship between intraabdominal fat accumulation and the cardiac abnormalities associated with obesity. Since increased upper-body and intra-abdominal fat accumulation relates to the presence of insulin resistance even without significant overall obesity, these investigators speculated that the cardiac dysfunction observed in obese individuals may be related to insulin resistance.

## A Summary

Obesity is recognized as an independent risk factor for the development of cardiovascular disease. Obesity is also associated with the development of cardiac dysfunction. Obese individuals have an increased risk for developing left ventricular dilatation, impaired systolic and diastolic dysfunction, and the development of left ventricular hypertrophy.

## VI MANAGEMENT OF THE OBESE INDIVIDUAL WITH HYPERTENSION

Weight loss is the cornerstone of hypertensive management in the obese individual. Weight loss in both adolescents and adults improves all of the cardiovascular abnormalities associated with obesity, including hypertension, dyslipemia, sodium retention, structural abnormalities in resistant vessels, and left ventricular hypertrophy and dysfunction. It is also important to realize that the method by which weight loss is accomplished is important. Although weight loss in general

results in a drop in resting systolic/diastolic blood pressure and heart rate, when the weight loss is incorporated with physical conditioning, the greatest decrease in resting systolic blood pressure, peak exercise diastolic pressure, and heart rate can be achieved (26). Similarly, a weight loss program that incorporates exercise along with caloric restriction produces the most favorable effects on insulin resistance (26,63), dyslipidemia (63,215), and vascular reactivity (26,98). Endurance training in obese and nonobese individuals improves insulin resistance in part by increasing muscle oxidative capacity and increasing capillary density (123,124). Most investigators believe the additive effect of exercise to weight loss is related to the fact that exercise improves insulin resistance independently of weight loss.

Although weight loss and exercise are the cornerstones of blood pressure management in obese hypertensive individuals, most obese individuals are either unable or unwilling to lose weight or are unable to keep from regaining lost weight. Therefore, pharmacological therapy is frequently required in the hypertensive obese individual. When choosing an antihypertensive agent, it is important to remember that, depending on the antihypertensive agents used, insulin resistance has been reported to improve, worsen, or remain unchanged. In general, thiazide diuretics (54,109,216) and  $\beta$ -blockers (54,109) are known to impair insulin sensitivity and glucose tolerance; calcium blockers do not seem to adversely effect carbohydrate metabolism (217–219); indapamide and potassium-sparing diuretics do not influence glucose homeostasis (220); and finally, angiotensin-converting enzyme inhibitors (109) and  $\alpha_1$ -blockers (110,221) may even improve glucose metabolism and insulin resistance. Rocchini et al. (171) have recently demonstrated that clonidine, a centrally acting sympathetic agent, not only improved the hypertension associated with obesity but also improved the insulin resistance. Guigliano et al. (222) demonstrated that transdermal clonidine was effective in reducing blood pressure and improving insulin resistance in hypertensive individuals with non-insulin-dependent diabetes mellitus. Based on these two preliminary studies, it would appear that clonidine or other, like drugs have a favorable profile for obese individuals with hypertension.

In addition to their unfavorable effect on insulin resistance, thiazide diuretics impair pancreatic insulin secretion (223,224) and increase LDL cholesterol and total cholesterol (109,225).  $\beta$ -Blockers are associated with a two- to threefold incidence of inducing diabetes mellitus (226) and are associated with a significant

lowering of HDL cholesterol (227,228). However, despite the different pharmacologic profiles of the antihypertensive drugs, there exists no clear recommendation for obese hypertensive individuals. Although  $\beta$ -blockers adversely effect the dyslipemia of obesity, Schneider et al. (229) reported that in obese hypertensive individuals the  $\beta$ -blocker metoprolol decreased diastolic blood pressure to a greater extent than in those individuals receiving calcium channel blocker isradipine. Conversely, these investigators found that isradipine was more effective than metoprolol in reducing blood pressure in lean hypertensives. Frohlich (230) randomly assigned obese and lean hypertensive subjects to receive either a  $\beta$ -blocker or a calcium channel blocker. This study clearly suggested that the probability of excellent blood pressure control was greater when metoprolol was given to obese individuals and isradipine to nonobese subjects. Thus, when deciding on the use of an antihypertensive in an obese individual, one must also take into account the lipid profile of the patient and the presence or risk of developing diabetes mellitus.

Finally, there are increasing data that confirm that angiotensin-converting enzyme inhibitors have specific benefit in individuals with diabetes, atherosclerosis, left ventricular dysfunction, and renal insufficiency (231). There are two other classes of agents, biguanides (metformin) and thiazolidinediones (pioglitazone, rosiglitazone, and troglitazone), that also appear to reverse insulin resistance, hypertension, and dyslipemia (232,233). However, troglitazone recently has been associated with significant liver toxicity (234). It is too early to know the role that these or similar agents will have in the treatment of obesity hypertension.

## VII SUMMARY

Although weight loss is the cornerstone of hypertensive management in the obese individual, many individuals will also require pharmacologic therapy. When choosing an antihypertensive medication it is important to individualize the agent to the patient. Some agents such as thiazide diuretics and  $\beta$ -blockers can impair glucose tolerance and adversely alter plasma lipid levels, whereas angiotensin-converting enzyme inhibitors and centrally acting sympathetic agents improve both the hypertension and insulin resistance associated with obesity. Finally, angiotensin-converting enzyme inhibitors are also effective in reducing the development of congestive heart failure and reducing cardiovascular mortality.

### I ASSOCIATION BETWEEN OBESITY AND DIABETES

Obesity is rare in insulin-dependent type 1 diabetes mellitus, but is common in type 2, non-insulin-dependent, diabetes mellitus (DM). About 85% of diabetics can be classified as type 2, and of these an average of 70% are overweight, ranging from a low of 50% to a high of 90%, depending on age, gender, and race (1).

An initial observation that obesity and diabetes mellitus are associated was made by John (2) in 1929. Also, early on, it was observed that weight loss improves glucose control (3). West and Kalbfleisch (4), in the 1960s, in a series of population studies including many geographical areas, races, and cultures, noted a strong association between the prevalence of diabetes and overweight. They proposed that the largest environmental influence on the prevalence of diabetes in a population group was the degree of obesity present in that community (5). In some of these populations, diabetes was found to be as much as threefold higher in females than in males. Controlling for adiposity abolished these sex differences. In the Bedford diabetes survey of 1962, Fowler et al. (6) found that whereas in individuals <40 years of age there was no relation of weight to the prevalence of diabetes, in the 40-to-70-year-old age range the persons with diabetes were fatter. Baird et al. (7) investigated siblings of diabetic patients and siblings of nondiabetic matched controls and found

that siblings of diabetics had a threefold higher prevalence of diabetes, but those with the highest prevalence were the obese siblings of nonobese diabetic probands. More recently, Knowler et al. (8) have shown that in the Pima Indian population, the likelihood of developing diabetes rises steeply with increasing fatness (Fig. 1).

Finally, the seriousness of the present status in the United States, with regard to the increase in prevalence of type 2 diabetes mellitus, is reflected in the data from the NHANES (National Health Examination Survey) III data (1988–1994). Type 2 diabetes mellitus showed a strong increase in prevalence with increasing degree of overweight among both younger and older subjects. The prevalence was a staggering five times higher for men and 8.3 times higher for women in the most obese group compared to normal-weight individuals. As opposed to earlier studies, the prevalence ratio associated with elevated weight was three- to fourfold greater among younger overweight men and women (Fig. 2) (5–9).

There have been prospective studies in a number of countries, including the United States (10), Norway (11), Sweden (12), and Israel (13) which have shown that increasing weight increases the risk of diabetes. In the Nurses' Health Study, which has followed 114,824 women for 14 years, it has also been found that the risk of developing diabetes increases as body mass index (BMI) increases (14,15). Weight gain of even 7.0–10.9 kg after the age of 18 years was associated with a twofold increase in the risk for diabetes. It is important

**Figure 1** Age- and sex-adjusted incidence of diabetes by body mass index with 95% confidence intervals. The data are adjusted by age and sex using the 1980 U.S. white population as a standard to give average incidence rates according to body mass index. (From Ref. 8.)

to note that this rise begins at levels of BMI of 22, considered generally to be a rather lean weight. These investigators observed that weight gain after the age of 18 years could be correlated to the increased incidence of diabetes, with a greater risk as the baseline of weight from which an individual started increased and also with a greater risk as weight gain increased (Fig. 3) (14,15). Other studies have found a similar risk for diabetes with increasing weight gain (16) and duration of overweight (17,18).

It is important to note that, recently, investigators analyzing results of 16 years of follow-up in the Nurses' Health Study found that lack of exercise, a poor diet, and current smoking were significantly associated with increased risk of diabetes, even after adjustment for BMI (19).

## II OBESITY AS ONE OF THE MAIN FACTORS IN THE TYPE 2 GLOBAL DIABETES EPIDEMIC

The recent global type 2 diabetes epidemic has been most pronounced in non-Europid populations. This was evident in studies from Native American and Canadian communities, Pacific and Indian Ocean island populations (20), groups in India (21), and Australian Aboriginal communities (22). Zimmet et al. recently summarized the magnitude and the potential reasons for this epidemic (23). In the Pacific Island of Nauru,

**Figure 2** Age-adjusted relative risk for diabetes mellitus during 14 years of follow-up and weight change between age 18 years and 1976. (From Ref. 14.)

diabetes is present in ~40% of adults while it was virtually unknown 50 years ago (24). The highest yet reported prevalence in people of Chinese extraction comes from Mauritius. In addition, Asian Indians and Creoles experienced high rates of diabetes and a notable secular increase between 1987 and 1998 (25). Prevalence of type 2 diabetes doubled between 1984 and 1992 in Singaporean Chinese (26) and is very high in Taiwan (27). The potential for increases in the number of cases of diabetes is greatest in Asia (28). According to one estimate the number of individuals with type 2 diabetes in China will increase from 8 million in 1996 to 32 million by 2010 (23).

The current view on the reasons for this epidemic is that, apart from heightened genetic susceptibility of

**Figure 3** Prevalence of type 2 diabetes mellitus by obesity class, in men and women. Data from the Third National Health and Nutrition Examination Survey (NHANES III). (From Ref. 9.)

certain ethnic groups, environmental and behavioral factors such as sedentary lifestyle, poor nutrition, and obesity play an important role (23,29). One of the major debates in diabetes etiology is the issue of “thrifty genotype versus thrifty phenotype.”

The thrifty genotype hypothesis provides an explanation for the very high prevalence of obesity and type 2 diabetes in the American Pima Indians, Australian Aborigines, and Pacific Islanders. Susceptibility for disease could result from an evolutionarily advantageous thrifty genotype that promoted fat deposition and storage of calories in times of plenty for use in times of scarcity. The present plentiful supply of a diet rich in simple carbohydrates and saturated fats and the reduction of occupational and leisure-based physical activity cause the previously favorable metabolic profile seen in “survivors” to result in obesity and type 2 diabetes. The thrifty phenotype hypothesis is based on the epidemiological observations linking low birth weight with the risk of adult disease (obesity, diabetes, and hypertension). A combination of the two may also be possible and more research is needed to clarify this problem (23).

### III INFLUENCE OF THE DISTRIBUTION OF BODY FAT

The possibility of a relationship between the distribution of body fat and diabetes was first raised by Jean Vague (30), who clinically observed and reported in 1947 the occurrence of two kinds of “obesities”: the android, “apple” shape or predominantly upper-body distribution of the adipose tissue, and the gynoid, “pear” shape or predominantly lower-body distribution of the adipose tissue. Subsequent cross-sectional and prospective studies have linked diabetes mellitus, dyslipidemia, and other cardiovascular risk factors to the distribution of body fat.

Feldman et al. (31), studying a group of more than 7000 people at multiple sites, found that those with diabetes were fatter and also had a more central distribution of their fat. They suggested that in diabetes there is an abnormality in hormone balance that causes women to be more like men in central fat distribution and exaggerates this effect in men. A study of more than 15,000 American women showed that clinical diabetes was related directly not only to increasing obesity but also to increasing central obesity. Women with both upper-body fat predominance and severe obesity had a relative risk of diabetes 10.3 times as great as nonobese subjects with lower-body fat predominance (32).

Distribution of body fat has been measured anthropometrically by four methods: (1) the ratio of the waist

circumference to the hip circumference (WHR); (2) the “centrality index,” i.e., the adipose tissue of the trunk versus that of the limbs expressed as the subscapular versus the triceps skinfold ratio (SSF/TSF); (3) the waist versus the thigh circumference ratio; or (4) the waist circumference in absolute terms.

The first reports in large population samples prospectively linking fat distribution to diabetes came from Sweden. Ohlson et al. (33) reported that WHR was an independent risk factor for the development of diabetes in men followed for 13.5 years in Göteborg, Sweden, and Lundgren et al. (34) reported that diabetes mellitus and an increase in fasting blood glucose were independently predicted by the WHR measured 13 years prior in women from Göteborg.

In the United States, the influence of body fat distribution on the incidence and prevalence of type 2 DM was studied in Mexican-Americans. This population has the second highest incidence of diabetes in the United States after the Pima Indians. Mexican-Americans with type 2 DM were found to have a history of faster adult weight gain after the age of 18, to attain a higher weight at an earlier age, and to have more trunk fat as measured by subscapular skinfold (SSF) and less leg fat than nondiabetics (35). In the San Antonio Heart Study, the WHR was better associated with type 2 DM than was the SSF/TSF overall in the Mexican-American population; however, in women, both the WHR and the SSF/TSF were associated with increased prevalence of type 2 DM (36). Prospectively, in the San Antonio Heart Study, men and women with an upper-body fat distribution measured by the highest tertile of the ratio of the SSF/TSF were more likely to get diabetes (37,38) than the other subjects. The relationship of the centrality index to conversion to diabetes was probably mediated by the relationship with insulin resistance since, in multivariate analysis, it no longer remained associated once fasting insulin and glucose were taken into account.

Results of Caucasian population studies in the United States, such as the non-Hispanic white cohort of the San Antonio Heart Study, are also consistent with a relationship between the WHR and the incidence of type 2 DM (36). In another study, of a population of 41,837 women aged 55–69 years of age, followed over 2-year period in Iowa, body fat distribution determined by self-measurement of the WHR was significantly and independently predictive of type 2 DM development (39).

Although the effect that WHR has on the development of diabetes over and above the impact of BMI is undisputed, the magnitude of this effect is controversial, with some groups reporting only a marginal effect, confined to the top 10% of the WHR distribution

(15). This may be due to the complex relationship between WHR and the development of diabetes, with insulin resistance and abdominal fat amount and metabolism both playing an important role. Waist circumference may better reflect the overall degree of insulin resistance and abdominal adiposity than WHR. Waist circumference has been found to be a better marker of abdominal fat content than WHR (40,41), across gender and BMI range (42), and across ethnic groups (43). Whether WHR imparts any independent information about disease risk beyond waist circumference is uncertain, but between the two, the waist circumference appears to carry greater prognostic significance (44,45).

#### IV INSULIN RESISTANCE

The reason for the relationship of obesity to diabetes mellitus is not totally clear, but two facts are incontrovertible. The accretion of excess body fat is associated with increasing insulin resistance (46), and insulin resistance is a predisposing factor for diabetes (47).

The phenomenon of excessive blood insulin level in obesity, both basal and postprandially, is one evidence of the fact that an insulin resistance or insensitivity is present. Studies of intra-arterial insulin infusions in the forearm have revealed insulin resistance in both adipose tissue and muscle (48). Also, the insulin insensitivity of muscle in obesity extends to amino acid metabolism. The amino acids usually most sensitive to the action of insulin are elevated in the blood, despite the hyperinsulinism (49).

There is experimental evidence that the liver in obese subjects also manifests insulin resistance. Obese subjects, when compared to lean subjects, have a higher splanchnic uptake of glucose precursors, have a smaller inhibition in splanchnic glucose output with equivalent insulin increases, and, if glucose is infused at rates causing comparable inhibition in splanchnic glucose output, have a greater increase in insulin (50). This is manifest in the liver by increased hepatic glucose output and in the periphery by a decreased glucose uptake by peripheral tissues, primarily muscle and adipose tissue. This is caused by both receptor and postreceptor defects in insulin action. Whether an individual with insulin resistance develops impaired glucose tolerance or frank diabetes depends on the ability of the beta cells of the pancreas to compensate for the insulin resistance by secreting more insulin. That individual whose beta cells can keep up remains euglycemic though hyperinsulinemic, while that individual whose beta cells begin to exhaust develops hyperglycemia (51).

#### V INSULIN RECEPTORS

Insulin signaling at the cellular level is mediated by the binding of insulin to a specific receptor. Insulin binding stimulates autophosphorylation of the intracellular region of the receptor  $\beta$ -subunit (52). Studies have shown that obesity is a major contributory factor for the development of reduced insulin receptor activity (53,54). In obese persons, there is a decrease in the number of insulin receptors on the cell membranes of insulin-sensitive target cells, such as adipocytes (55). This downregulation of the number of insulin receptors is thought to occur as a result of the increased circulating insulin levels (55), although it might be a primary defect. It is likely that this occurs by increased receptor internalization (56). Insulin receptor binding is thus decreased.

#### VI POSTRECEPTOR EFFECTS

After insulin binds to its receptor, the autophosphorylation results in activation of the tyrosine kinase activity causing a conformational change that allows ATP and receptor substrates to reach the catalytic site (57,58). The activated insulin receptor kinase results in phosphorylated IRS proteins (insulin receptor substrate proteins) on tyrosine residues. These phosphorylated IRS proteins serve as docking sites for downstream effectors (postreceptor events). Such an effector is phosphatidylinositol 3-kinase (PI 3-kinase). This mediates most metabolic responses to insulin, i.e., protein and glycogen synthesis, antilipolysis, and antiapoptosis, as well as glucose transport, which leads to the utilization of glucose, both oxidation and storage (58,59).

While the insulin receptor is downregulated in human obesity, there is no further decrease in its activity in liver and muscle of patients with type 2 diabetes, suggesting that the more severe insulin resistance in these patients, when present, is primarily of postreceptor nature (53,60). Insulin receptor phosphorylation, IRS-1 phosphorylation, and PI 3-kinase activity are decreased in intact skeletal muscle strips from obese subjects (61). Some investigators have shown that, overall, the muscle is as equally and severely resistant to the action of insulin in those obese patients without diabetes as in those with diabetes (60). Others have shown that the PI 3-kinase is more severely reduced in patients with type 2 diabetes (61). Furthermore, adipose tissue is more insulin resistant in type 2 DM than it is in obesity (60), primarily owing to decreased insulin receptor tyrosine kinase activity in the tissue of patients with type 2 diabetes (62). Present working hypotheses for obesity-linked kinase activity inhibition are elevation in tyrosine

phosphatase activity or enhanced Ser/Thr phosphorylation of the receptor that impairs its tyrosine kinase activity (58,59).

Glucose transport in insulin-sensitive cells is greatly enhanced by insulin. This occurs by translocation of glucose transporters from the intracellular pool to the plasma membrane (63). A PI 3-kinase-dependent pathway facilitates the translocation of the insulin-dependent glucose transporter 4 (Glut 4) (59). In obesity and diabetes, glucose transporters in adipose tissue are decreased due to pretranslational suppression of Glut 4 transporter gene (64). However, in muscle tissue there is impaired Glut 4 function and/or translocation to the cell membrane surface and not transporter depletion (65).

Glucose disposal is impaired in obese persons (55, 66). Use of indirect calorimetry during insulin clamp studies has allowed measurement of glucose uptake in human subjects. The difference between glucose oxidation and glucose disposal, that is, the nonoxidative glucose disposal, is used to measure glucose storage as glycogen (66,67), since there is little net glucose conversion to lipid and little of the glucose that is taken up by muscle is released as lactate. Both glucose oxidation and glucose storage are impaired in obesity, and more so in diabetes. However, the major defect of glucose metabolism is in glucose storage, since oxidation is less impaired (68). This is shown in Figure 4 taken from one of our studies (69).

Defects in glycogen synthase activity (70,71), hexokinase II (72,73), and glucose transport (72,74,75) have all

**Figure 4** Total glucose disposal during euglycemic hyperinsulinemic clamp. Values are means  $\pm$  SE partitioned into glucose oxidation (determined by indirect calorimetry) and nonoxidative glucose disposal (storage).  $P < .001$  for glucose oxidation, glucose storage, and total glucose disposal: lean > obese > diabetic men. (From Ref. 69.)

been implicated in the loss of muscle glycogen synthesis in obesity and type 2 diabetes. Strong evidence pointing to glucose transport as the primary defect has been recently brought forth. In a series of elegant studies, Shulman et al. (76) showed that impaired glucose transport is the rate-controlling step for impaired insulin-stimulated muscle glycogen synthesis in patients with type DM and their lean nondiabetic offspring (77,78).

## VII FREE FATTY ACIDS

As a rule, patients with obesity, and particularly as they develop diabetes, have elevated levels of free fatty acids (FFA) (47). The concept that elevated FFA play a key role in the development of insulin resistance in obesity and type 2 diabetes was first proposed by Randle (79). The theory stated that increased availability of FFA will increase fat oxidation, resulting in decreased glucose oxidation as well as impairment of glucose uptake. Recent studies by Boden et al. (80) and Shulman et al. (76) have clarified the sequence of these events, confirming nevertheless that elevated FFA play an important role in the impaired glucose utilization observed in obesity and type 2 diabetes.

Specifically, studies by Boden et al. suggest that chronic elevation of FFA will produce impaired glucose uptake by inhibition of glucose transport and phosphorylation, which will be followed by a decrease in the ability to store and oxidize glucose (81–83). Shulman et al. further demonstrated that the rate-controlling step for fatty acid-induced insulin resistance is glucose transport (84–86). They hypothesized that this could be a result of either a direct effect of increased intracellular FFA (or an FFA metabolite) on glucose transporters, or indirectly, from alterations in upstream signaling events such as reduced PI-3-kinase or other serine/kinase activities (87).

Other deleterious effects of high levels of FFA in obesity may be stimulation of the liver to increase gluconeogenesis, thereby enhancing hepatic glucose output (88,89). The net effect of these two phenomena is to increase circulating glucose levels and stress the beta-cell insulin secretory system (80).

## VIII UPPER BODY FAT DISTRIBUTION AND VISCERAL ADIPOSITY

The large population studies on fat distribution described earlier raise the question of the mechanisms linking body fat distribution to type 2 diabetes. While a few of these mechanisms have been clarified, others are still unclear and are being studied.

Kissebah and associates published several papers relating WHR to a decreased insulin action at the muscle (90), liver (91), and adipose tissue level (92) in obese nondiabetic women. They also found an association between increased WHR and hyperinsulinemia, due to both increased insulin production and decreased hepatic insulin extraction (93). Evans et al. (90) showed that insulin binding in muscle and the sensitivity of the muscle to insulin action, as measured by the activity of glycogen synthase in muscle, decreased independently with obesity and with an increase in WHR. This can contribute to decreased glucose storage and, if plasma insulin secretory response cannot increase appropriately, development of diabetes.

Björntorp postulated that the unfavorable effects of upper body fat distribution, as measured by the WHR, are due to the accumulation of visceral adipose tissue (VAT), increased FFA flux to the liver, and subsequent hyperinsulinemia and insulin resistance in liver, muscle, and subcutaneous adipose tissue (94–96). VAT accumulation measured by CT scan as well as the visceral to the subcutaneous adipose tissue ratio (VAT/SAT) at the abdominal level were indeed found to be independently associated with glucose intolerance in males participating in the Normative Aging Study in the United States (97). VAT accumulation was found to be associated with glucose intolerance in premenopausal women (40) and in men in Canada (98) and with glucose intolerance in Japanese men and women (99). These associations were independent of the overall degree of obesity. In addition, in a cohort of Japanese-Americans, increased VAT was shown to predict the development of type 2 diabetes after 30 months of follow-up. This association was no longer significant after adjusting for the initial C-peptide level (hyperinsulinemia) (100).

The pathogenesis of the relationship of VAT with type 2 diabetes is not entirely clear. VAT has been associated with insulin resistance in women (43,101, 102) and men (103); however, this association is not always independent of the overall fat mass accumulation (43,104). On the other hand, the associations of VAT with hyperinsulinemia has been consistently independent of the degree of overall fatness (43,105).

Some researchers have postulated that the role of VAT in the associations between abdominal obesity and the insulin resistance syndrome is not as important as the role of the abdominal subcutaneous adipose tissue (SAT). Associations between the amount of abdominal subcutaneous fat (SAT) and insulin resistance have been recently reported (104,106,107), independent of the amount of VAT. Specifically, it appears that deep subcutaneous fat (107,108) and fat closer to muscle

fascia as well as fat accumulated inside the myocytes may have an even closer association with insulin resistance (107,108). These findings are also consistent with results of *in vivo* lipolysis studies in women with upper-body and visceral obesity (109,110) which have shown that the source of excess FFA in abdominal obesity is the subcutaneous adipose tissue.

Work that we and others have published recently may bring some light to the controversial role of VAT vs. SAT in the development of insulin resistance and type 2 diabetes in obese individuals. Specifically, lipolysis in SAT was increased in women with visceral obesity independently of the overall degree of obesity, both during insulin suppression (110,111) and epinephrine stimulation (112,113). Thus we, and others (114), have postulated that the relationship between VAT and insulin resistance may be explained by their common correlate: the upper-body subcutaneous fat.

## **IX ROLE OF TUMOR NECROSIS FACTOR (TNF)- $\alpha$ AND OTHER CYTOKINES AND ADIPOSE TISSUE SECRETORY PRODUCTS IN THE PATHOGENESIS OF OBESITY-ASSOCIATED INSULIN RESISTANCE**

Recently, TNF $\alpha$  has emerged as possibly playing a key role in the insulin resistance of obesity and type 2 DM (115,116). TNF $\alpha$  is a powerful inhibitor of insulin action in cultured cells, increasing the Ser phosphorylation of IRS-1 and IRS-2 and reducing the ability of these molecules to dock with the insulin receptor and interact with downstream pathways such as the PI 3-kinase (58,117,118). TNF $\alpha$  expression and secretion are elevated in adipose tissue of multiple experimental models of obesity and in abdominal fat and muscle tissue of obese individuals where they correlate with the degree of obesity, the levels of plasma insulin, and the degree of insulin insensitivity, and decrease with weight loss (116,119,120). Circulating levels of TNF $\alpha$  are increased in obesity and decrease with weight reduction (121). However, they do not correlate with the individual degree of insulin sensitivity (122). The current hypothesis is that TNF $\alpha$  acts in a paracrine fashion in adipose tissue and muscle (58,122) either directly on the insulin signaling cascade (123), or indirectly via stimulation of secretion of FFA or other cytokines such as leptin and/or interleukin (IL)-6 (122).

While the presence of a relationship between plasma leptin levels and/or leptin production in adipose tissue and insulin sensitivity is still controversial (59), Kern et

al. have recently demonstrated that plasma IL-6 is related with the degree of insulin insensitivity to insulin action *in vivo* (122). They hypothesize that perhaps IL-6 represents a hormonal factor that induces muscle insulin resistance.

Other adipose secretory products identified recently and implicated in obesity-associated insulin resistance are adiponectin and resistin. Adiponectin is a novel adipose-specific protein with putative antiatherogenic and anti-inflammatory effects. Its plasma concentration was found to be decreased in individuals with obesity and type 2 DM, and was more closely associated with the degree of insulin resistance and hyperinsulinemia than with the degree of adiposity or glucose intolerance (124,125). Resistin is a newly described circulating hormone expressed primarily in adipocytes and shown to antagonize insulin action in mice (126). However, resistin gene expression in human adipocytes or muscle is very low or absent and, when present, does not appear to relate with the degree of insulin resistance (127,128).

## X INSULIN SECRETION

It is generally believed that increased production of insulin by the beta cells of the pancreas is a response to the insulin resistance of obesity. In most studies, obese persons are found to be hyperinsulinemic (129,130). In general, the fatter an individual, the higher the basal or fasting insulin (131). This basal insulin is correlated to adiposity and the degree of overweight, and is related to the increasing insulin resistance that occurs with increasing adiposity (132). The degree of insulin response to glucose or other stimuli is related to basal insulin secretory levels and therefore can be correlated closely with the degree of obesity (133). This correlation between insulin response and obesity disappears if the response is expressed as a percentage of the basal value; i.e., the insulin response as a percentage of the basal value does not rise higher in the obese than in lean subjects.

In 1200 nondiabetic, normotensive European individuals the relationship between insulin resistance and insulin secretion was nonlinear (132); as insulin sensitivity declined, insulin secretion increased more than proportionally to compensate for the insulin resistance. Obesity shifted the curve upward. The relationship between insulin resistance or insulin secretion and BMI in this study was linear. The prevalence of insulin resistance and hypersecretion were quantitated in this study by defining resistance as the bottom 10% for insulin resistance and hypersecretion as the top 10%

for insulin secretion. It became apparent that the prevalence of insulin hypersecretion was greater than the prevalence of insulin resistance in each category of BMI (Fig. 5) (132). In Pima Indians, there is an upper limit to this relation between adiposity and insulin secretory response. There is increasing insulin resistance as the percent of fat in the body increases up to about 35–40%; after that, insulin resistance does not increase further and insulin levels no longer rise (134).

The documented aberrations in insulin secretion in obese individuals, coupled with other hormonal abnormalities such as poor response to growth hormone and glucagon stimulation, made it unclear whether the hormonal defects seen in obesity were primary or a consequence of the obesity. The hormonal abnormalities are thought to be a consequence of the obesity since they revert to normal with effective weight loss and are found to appear after prolonged overfeeding of normal volunteers to an obese state (135). However, it is not known whether insulin hypersecretion is an earlier event at the very origin of weight gain, reflecting perhaps a central nervous system derangement. For example, hyperinsulinism may be a result, at least in part, of dietary factors rather than exclusively a consequence of insulin antagonism. Excess calories (136) and excess carbohydrate (137) may enhance insulin secretory response.

In those obese individuals who begin to develop abnormal glucose metabolism, the postprandial increase of insulin over basal values is actually decreased in comparison to normal subjects. This impairment is first observed as patients move from normal to impaired

**Figure 5** Prevalence of insulin resistance and insulin hypersecretion as a function of body mass index in nondiabetic, normotensive Caucasian subjects. (From Ref. 132.)

glucose tolerance to frank diabetes. Initially there is a reduction in overall insulin response (138). Subsequently, when fasting glucose begins to rise, the early phase of insulin response is lost (139), and as carbohydrate tolerance continues to deteriorate, all of the insulin response is further reduced. Most experimental data suggest that the first phase of insulin response is initially affected (140). However, there have been some studies suggesting an impairment of the second phase response, or of both (141). Even though an obese diabetic may be secreting a greater amount of insulin than a lean diabetic person, it will not be enough to maintain normal glucose tolerance, and the insulin response will be less than that of an obese person with equal adiposity who has normal glucose tolerance.

At some point, when certain individuals cannot keep up with the required increased insulin levels and become relatively hypoinsulinemic, hyperglycemia and frank diabetes supervene. The onset of hyperglycemia is not predictable in a particular individual, and seems to be determined by genetic predisposition. However, studies have suggested that the duration of obesity rather than the degree of obesity can best be correlated with carbohydrate intolerance in both obese adults and obese children (142). The genetic abnormality is likely to be an intrinsic defect in the beta cell (51,143). In fact, there is probably a heterogeneity of defects. For example, the abnormality in maturity-onset diabetes of the young is in the glucokinase gene, leading to impaired insulin release (144).

Weyer et al. (145) have recently reported on the importance of maintaining insulin secretory response in the development of type 2 DM in obese Pima Indians followed over a period of 4–7 years. All subjects followed who gained weight had a worsening of their systemic insulin-stimulated glucose disposal. However, those who also had a worsening of their insulin secretory response became glucose intolerant (IGT). Those who developed type 2 diabetes had a further increase in weight gain and worsening of both insulin-stimulated glucose disposal and an increase in the basal endogenous glucose production (145).

## XI EFFECT OF EXERCISE

Obese individuals tend to lead a sedentary existence, and recent epidemiological evidence has reported that a sedentary lifestyle is a risk factor for the development of diabetes. The prevalence of both impaired glucose tolerance and type 2 DM is higher in inactive than active persons (146). In a prospective study of University of

Pennsylvania male alumni, followed over 14 years, the age-adjusted incidence rates of diabetes decreased as the reported activity increased (147). This was also found in the Nurses' Health Study (148). Physical activity is inversely associated with obesity and central fat distribution, and physical training can reduce both of these conditions (149,150). In a prospective study of diabetes prevention in persons with impaired glucose tolerance, a 5-year program of diet and exercise showed that those individuals taking part in the diet-and-exercise program had less than half the progression rate to diabetes than the controls for whom no intervention was planned (151). The data are thus very suggestive of a relationship between activity and the prevention or delay of onset of type 2 DM. For this to be adequately confirmed, a randomized control trial would need to be done. So far, randomized interventional studies of lifestyle changes (both regarding diet and an increase in physical activity) in high-risk overweight patients have shown that weight reduction significantly reduces the incidence of type 2 diabetes (152,153).

The relationship between inactivity and risk for diabetes is likely to be at least partially attributed to decreased insulin sensitivity. Insulin sensitivity could be improved by exercise independently from weight reduction and changes in body composition. The muscle, liver, and fat contribute to the improvement of insulin sensitivity induced by physical exercise (154–156).

## XII MACROVASCULAR DISEASE RISK

Once diabetes manifests itself, the nature of the disease can be similar to that in nonobese individuals, and all types of complications can ensue. Obesity, even independent of diabetes, is a risk factor for hypertension (157) and cardiovascular disease (158,159). When it is combined with diabetes, the risk of acquiring these illnesses is therefore greater, leading to a significantly increased morbidity and mortality (10).

The hyperinsulinemia, which occurs in obesity and in type 2 DM, is likely to abet the hypertension. Insulin has been found to be abnormally high in patients with essential hypertension, many of who manifest a degree of insulin resistance (160,161). Hypertension and glucose intolerance show a highly significant association from the mildest levels of both conditions (162). The hormone exerts a powerful effect on the kidney, increasing sodium reabsorption and thus expanding plasma volume (163).

The high levels of LDL cholesterol and triglycerides and the low levels of HDL cholesterol that are common

in diabetic patients are likely to play a role in the pathogenesis of accelerated macrovascular disease (164). These abnormalities in circulating lipids are already present in obese individuals before the development of type 2 DM. In addition, as mentioned above, obese patients tend to run higher levels of FFA (47). This is particularly true of those obese individuals with central obesity (165). The enhanced FFA flux, along with the hyperinsulinemia and the ready availability of glycerol phosphate, greatly enhances the production of triglycerides in the liver. The triglycerides are packaged in the liver primarily as very low density lipoproteins (VLDL) and released into the circulation. Lipoprotein lipase released from endothelial cells in capillaries of the adipose depot helps to hydrolyze the VLDL, clear them from the circulation, and store them in the adipose tissue (166). In obesity and type 2 DM, lipoprotein lipase activity is impaired and the clearance of VLDL is delayed (167). Furthermore, in the normal process of HDL production, mature HDL is made from nascent HDL interaction with triglyceride-rich lipoprotein and lipoprotein lipase. This is defective in obese, insulin-resistant persons (168).

The final abnormality in lipids in this group of patients is the tendency to have an increased amount of small, dense LDL particles (169,170). The influence of modifiers such as hepatic lipase and cholesteryl ester transfer proteins on VLDL and HDL metabolism in patients with insulin resistance and central obesity leads to increased levels of circulating small, dense LDL cholesterol particles (171). These lipoprotein modifications are associated with atherosclerotic cardiovascular disease (ASCVD) (172). Recently it was proposed that, in the general population, this phenotype (low levels of HDL cholesterol and small dense LDL) may not be at increased risk for ASCVD unless associated with insulin resistance and an increased production of apolipoprotein B (172,173).

In type 2 diabetes, the LDL cholesterol may be oxidized and/or glycated, enhancing its atherogenicity (174). These glycated or oxidized particles are more atherogenic than larger particles and may be very important in the pathogenesis of the atherosclerosis that accompanies type 2 DM. Correction of the insulin resistance of obesity and type 2 DM with vigorous dietary and pharmacological means improves blood lipids and also hyperglycemia (175). Moreover, the current recommendations are that all patients with diabetes have reductions in LDL cholesterol to < 100 mg/dL.

Macrovascular disease is the leading cause of death in obese individuals with type 2 DM. The improvement of glucose control may, in itself, seem to have a small

effect in improving the morbidity and mortality from coronary artery disease (CAD). The proof that more and/or near-optimal control of glycemia results in a reduction of macrovascular disease remains to be established (171).

It has been suggested by numerous investigators that the prevailing elevated insulin levels in these people may predispose them to CAD. A study comparing cardiovascular risk factor in normoinsulinemic and hyperinsulinemic individuals found that the hyperinsulinemic persons manifest higher triglycerides, lower HDL cholesterol, higher total cholesterol, and higher mean blood pressure (176). In addition, there have been three large epidemiological studies that have shown an association with either fasting or stimulated insulin and CAD (177–179). Monitoring risk factors in a longitudinal design, all three found an independent effect of insulin on coronary heart disease. Stout (180) has discussed the potential mechanism by which insulin may enhance the atherosclerotic process. These include increased growth factor activity leading to enhanced smooth muscle proliferation and connective tissue growth, formation of lipid plaques, and enhancing cholesterol uptake by plaque tissue. The current belief, however, is that this relationship is not cause and effect, but association (171).

Other factors that can enhance the progression of CAD in obese patients, which is abetted if they are diabetic also, are enhanced platelet aggregability, prolonged platelet survival time, and abnormal levels of plasminogen activator and plasminogen activator inhibitor 1 (181,182). These all enhance the risk of clotting in atherosclerotic blood vessels. Also, at present, much attention is being given to the relationship between endothelial dysfunction and macrovascular disease in patients with type 2 diabetes (171).

### XIII MANAGEMENT OF THE OBESE DIABETIC PATIENT

As previously mentioned, obesity is present in the great majority of patients with type 2 DM. When present, obesity complicates the management of diabetes (183,184). Two issues arise in the management of the obese, insulin-resistant diabetic patient: first, glycemic control should be achieved but not at the expense of adipose tissue accumulation, especially in the visceral adipose depot with associated hyperinsulinemia and consequently, in the long run, more insulin resistance; and second, weight control must be achieved without losing sight of the need for tight glycemic control.

In the obese diabetic patient, as in any other diabetic patient, microvascular disease is primarily related to the presence of hyperglycemia (185). Uncontrolled glycemia is also responsible for an unfavorable lipoprotein pattern, an increase in glycosylation end products in all tissues, and an increased risk of thrombotic events (186). In the obese diabetic patients, tight glycemic control is thus warranted. The majority of the patients with type 2 DM are treated with oral hypoglycemic agents, which increase insulin sensitivity and enhance the beta-cell response to glucose (187). Exogenous insulin is usually necessary to control blood glucose in the obese diabetic patient when other therapeutic measures have failed to normalize blood glucose (187). Edelman et al. reviewed the use of insulin for the treatment of the type 2 diabetes (188). They concluded that obese diabetic patients could and should be evaluated for intensive insulin therapy. The candidates should be motivated and compliant and should be able to do home glucose monitoring and insulin administration. Combination therapy with insulin and oral agents can be a tool to normalize glycemia if oral agents fail. The adverse effects and potential risks of intensive insulin treatment include weight gain, which is directly associated with increased hyperinsulinemia (184,189–191). Hyperinsulinemia, as mentioned previously, has been associated with atherosclerotic risk factors, although a cause-and-effect relationship has not been proven (192). Weight control must therefore be an important part of diabetes management. It should be initiated early in the management of diabetes and it should continue throughout the duration of the treatment in the obese diabetic patient (193).

Caloric restriction and consequent weight loss in obese diabetic patients greatly improves their metabolic control because it results in improved insulin action in both liver and muscle, and frequently also results in improved beta-cell response to insulin secretory stimuli (193). In addition, weight control favorably changes cardiovascular disease risk factors such as hypertension and dyslipidemia (193). Weight control can and must be achieved through a medically supervised, moderately restricted-calorie diet and an exercise program with long-term maintenance goals (194). Recently, studies have shown that even moderate weight loss, when sustained, significantly improves the patient's metabolic profile and prolongs life expectancy (195–197). Patients with type 2 DM who underwent a 16-week lifestyle modification program and lost at least 5–10% of their initial body weight had significant improvement in HbA<sub>1c</sub> that was still present at a 1-year follow-up. These patients also had significant reductions in their need for diabetic medications (198).

One has to be careful of the effectiveness of weight-reducing programs for obese patients with type 2 diabetes treated with large doses of insulin. In such instances, the danger of hypoglycemia must be recognized, and there is a need for close monitoring of blood glucose with frequent decreases in insulin as necessary. Some of the postulated reasons for weight gain with insulin therapy are decreased thermogenesis (199,200) and increased appetite (201); thus, it may be impossible to achieve weight loss with caloric restriction unless insulin (or oral agents that increase insulin levels) are being adequately adjusted to the lower-calorie diet prescribed.

Various classes of hypoglycemic agents, including metformin and acarbose, have been identified that, when used to normalize blood glucose, do not produce weight gain, hypoglycemia, or hyperinsulinemia (202–204). In the United Kingdom Prospective Diabetes Study (UKPDS), a randomized, controlled trial comparing sulfonylurea, insulin, and metformin therapy in patients with newly diagnosed type 2 DM that could not be controlled with diet therapy, intensive blood glucose control with insulin or sulfonylurea therapy significantly decreased progression of microvascular disease. Patients allocated to insulin gained more weight and had more hypoglycemic events than did patients allocated to sulfonylurea. Obese patients allocated to metformin gained least weight and had the fewest hypoglycemic attacks (203,204).

A new class of antidiabetic agents, the thiazolidinediones (glitazones), reduce hepatic output of glucose and increase peripheral uptake of glucose, thus enhancing insulin sensitivity and reducing the amount of exogenous insulin needed (205,206). In studies comparing insulin-glitazone treatment with insulin alone, the combination therapy resulted in better glycemic control but was associated with greater weight gain. The significance of weight gain from glitazones is difficult to assess. Despite the weight gain, the glitazones may be beneficial in that they redistribute fat from visceral to subcutaneous areas. In addition, some of the weight gain is due to peripheral edema and to an increase in extracellular fluid (207).

It is our opinion that hypoglycemic agents that are not likely to produce weight gain should be used in the obese diabetic patient whenever possible—that is, when endogenous insulin secretion is adequate. If insulin secretagogues or exogenous insulin need to be used, it would be very beneficial to combine them with an insulin-sensitizing agent like metformin to minimize weight gain and the amount of insulin needed to achieve glycemic control.

For those obese diabetic patients who require insulin, the novel recombinant insulin glargine may be preferable to NPH. It has been shown that long acting basal insulin glargine given once daily at bedtime is as effective in achieving glycemic control as NPH. The advantage of insulin glargine is that it produces less weight gain (208). The lesser weight gain seen with insulin glargine is attributed to the less frequent hypoglycemia, and thus the decreased need to increase caloric supplementation (209). Use of insulin glargine compared with NPH is also associated with lower postdinner glucose levels.

Most obese patients are unable to maintain a modest long-term reduction in their weight. Obese patients with type 2 diabetes are even more resistant to weight loss because antidiabetic drugs such as insulin and sulfonylureas often promote weight gain. These patients would likely benefit from the addition of weight management drugs as adjunctive therapy to the traditional interventions of low-calorie diet, physical activity, and behavior management (210). Two drugs in particular have been recently developed—sibutramine and orlistat. Sibutramine is a selective serotonin and noradrenaline reuptake inhibitor. Blocking of serotonin reuptake produces the satiety enhancing effect of the drug. Inhibition of noradrenaline uptake increases thermogenesis via  $\beta$ -3-adrenoreceptors. This results in increased energy expenditure (211,212). Orlistat, a specific inhibitor of gastrointestinal lipases, decreases the absorption of dietary triglycerides from the GI tract in a dose-dependent manner. At the maximum effective dose of 120 mg TID, orlistat reduces the absorption of dietary fat by 30% (213).

Clinical trials have shown that the use of either agent as part of an integrated program of diet, exercise, and behavior management can help nearly one-third of patients with type 2 diabetes achieve a weight loss of up to 10% of initial body weight after 1 year. As a result of the weight loss, these patients also exhibited decreased HgbA1c, decreased blood pressure, and improved lipid profiles (210–212,214). Furthermore, studies on patients with impaired glucose tolerance have shown that orlistat improves glucose tolerance and decreases the risk of progression to type 2 diabetes (215).

Other agents presently studied for weight loss may prove to be beneficial in type 2 DM.  $\beta$ -3-Adrenoreceptor agonists were first tried in weight reduction more than a decade ago. Animal studies had shown that selective  $\beta$ -3-agonists can induce weight loss and produce a weight-independent improvement in insulin resistance and glucose intolerance. Currently new  $\beta$ -3-agonists are being developed that have a higher selectivity for humans (210). Leptin, an adipocyte-derived

hormone that is released into the bloodstream and acts as a satiety signal in the brain, has been shown to produce weight loss. In the first clinical study in humans, subcutaneous administration of a biosynthetic leptin was shown to reduce body fat and thus decrease weight in a dose-dependent manner (210). Thus, leptin is another potential weight-reducing agent for obese diabetic patients. Further studies on the safety and efficacy of leptin are needed before it can become an acceptable treatment for weight reduction (210).

Glucagonlike peptide (GLP-1), an insulinotropic gut hormone released into the bloodstream after eating, is being investigated as a promising new treatment for the obese patient with type 2 diabetes. Abnormalities in GLP-1 function are thought to contribute to the inappropriate insulin secretion seen in type 2 diabetes. This is supported by the fact that patients with type 2 diabetes have a reduced late intact GLP-1 response (216, 217). In patients with type 2 diabetes, administration of exogenous GLP-1 enhances the glucose responsiveness of pancreatic  $\beta$ -cells, resulting in increased insulin secretion and decreased plasma glucose (218,219). The stimulation of insulin secretion by GLP-1 is glucose dependent. Therefore, the risk of hypoglycemia with GLP-1 is low. GLP-1 has also been shown to improve glycemic control by decreasing the desire for food, delaying gastric emptying, reducing glucagon levels, and enhancing insulin sensitivity (220–222). GLP-1 also acts on the central nervous system to produce a satiating effect. Intracerebral injection of GLP-1 in normal and obese rats significantly reduces food intake and body weight (223). In patients with type 2 diabetes, GLP-1 infusion significantly enhances satiety and fullness, and reduces energy intake by 27% (224). In addition, stimulation of GLP-1 receptors in certain areas of the brain elicit strong taste aversions (225).

In a randomized, double-blind, placebo-controlled trial, 40 patients with type 2 diabetes were randomized to receive infusions of either placebo or GLP-1 at a rate of 4 ng/kg/min or 8 ng/kg/min for either 16 hr/d or 24 hr/d for a total of 7 days (226). All patients who received GLP-1 had significantly better average glucose and glucagons levels than the placebo group. The GLP-1 infusion at 8 ng/kg/min for 24 hr/d was the most efficacious dose. Those who received GLP-1 for only 16 hr/d had significantly higher nocturnal and fasting plasma glucose levels compared to those who were continuously infused for 24 hr every day. GLP-1 was well tolerated in these patients. GLP-1 and exendin-4, a more potent and longer-acting analog of GLP-1 that originates in the saliva of the Gila monster, has been shown to induce satiety and weight loss in rats (227). These agents are

being investigated as potential treatments for diabetes and obesity.

Obesity surgery has become a successful method of treating obesity, especially in the diabetic patient. Studies done in the United States and in Sweden have shown that most patients with type 2 diabetes who undergo bariatric gastric surgery develop normal glucose tolerance with 5–6 years of the surgery. This was attributed to the substantial amount of weight lost after the surgery (195,228). In one study, laparoscopic adjustable gastric banding was compared to nonsurgical treatment for obesity in patients with BMI > 35. Only the surgical patients had decreased BMI and HgbA1c. These patients also had more loss of visceral than subcutaneous adipose tissue (229).

In conclusion, the goal of the treatment for the obese diabetic patient is to achieve glycemic control, minimize weight gain, and minimize the amount of insulin required to achieve glycemic control. These goals can be achieved through effective lifestyle changes, use of antiobesity drugs such as orlistat and sibutramine, and, in particularly resistant cases of obesity, bariatric gastric surgery.

## Obesity and Gallbladder Disease

Cynthia W. Ko and Sum P. Lee

University of Washington, Seattle, Washington, U.S.A.

### I INTRODUCTION

Gallstones are a common problem in the general population, and have an even higher prevalence in the obese and in those losing weight. Complications of gallstones include biliary colic, acute and chronic cholecystitis, and pancreatitis. Three conditions are necessary for cholesterol gallstone formation: supersaturation of bile with cholesterol, nucleation of cholesterol crystals, and gallbladder stasis. In obese subjects, these pathogenetic mechanisms may be modified, leading to a predisposition to gallstone formation. This chapter will review the pathogenesis of cholesterol gallstones, and the effects of obesity and weight loss on gallbladder disease.

### II PATHOGENESIS OF CHOLESTEROL GALLSTONES

Bile is a complex substance composed of lipids, proteins, electrolytes, and water. There are three principal biliary lipids: cholesterol, bile acids, and phospholipids (primarily phosphatidylcholine). Many species of proteins are present, and they are derived from serum proteins as well as hepatocyte, bile duct, and gallbladder epithelial secretion. Gallstone formation is determined by the physical-chemical interactions of all of these components present in bile (1).

### A Synthesis and Secretion of Biliary Lipids

#### 1 Cholesterol

The liver is the site of primary site of cholesterol synthesis and lipoprotein metabolism in the body. Free cholesterol is synthesized in the hepatocyte endoplasmic reticulum. The rate-limiting enzyme in cholesterol synthesis is HMG-CoA reductase (2). Each day, several grams of cholesterol derived from lipoproteins are taken up by the liver. Cholesterol enters the liver in esterified form, is transported to the lysosomes, and is then converted into its free form. It is then transported to the endoplasmic reticulum and reesterified for storage. Cholesterol esters in the endoplasmic reticulum are continually undergoing hydrolysis, providing a constant supply of free cholesterol. This free cholesterol is the substrate pool for bile acid and lipoprotein synthesis and for secretion into bile. The rate of biliary excretion from this pool varies with the rate of bile salt and lipoprotein synthesis. Biliary cholesterol secretion is quantitatively correlated with bile salt secretion (2). However, the ratio of cholesterol to bile salts secreted increases as bile salt secretion decreases, in part explaining the finding of more saturated bile (higher cholesterol-to-bile salt ratio) at low bile flow rates. Cholesterol is believed to be secreted from the liver in the form of phospholipid-cholesterol vesicles (3). Leptin levels influence the amount of cholesterol secreted into bile in animal models (4), and gallstone prevalence is corre-

lated with serum leptin levels in humans, even after controlling for body mass index (5).

## 2 Bile Acids

Bile acids are synthesized from cholesterol through the rate-limiting enzyme cholesterol 7 $\alpha$ -hydroxylase, a microsomal enzyme. Bile acids, which are amphiphilic, solubilize and transport cholesterol. Two primary bile acids, chenodeoxycholic acid (3 $\alpha$ , 7 $\alpha$ ) (CDCA) and cholic acid (3 $\alpha$ , 7 $\alpha$ , 12 $\alpha$ ) (CA), are synthesized *in vivo*. The relative proportions of these are regulated by the activity of the enzyme 12 $\alpha$ -hydroxylase, which converts CDCA into CA. The cholesterol-carrying capacity of bile is influenced by the relative proportions of these two bile acids, since CA can solubilize less cholesterol than CDCA. 12 $\alpha$ -Hydroxylase can be induced by estrogens, resulting in higher proportions of CA and more lithogenic bile (1,2).

After synthesis, bile acids bind to carrier proteins for transport through the hepatocyte. Here, bile acids are conjugated with glycine and taurine, increasing their water solubility. They are then actively secreted by bile acid transporters located in the biliary canalicular surface of the hepatocyte. Bile acids are initially excreted as individual molecules. However, at the critical micellar concentration, they will aggregate to form micelles that are capable of solubilizing cholesterol and phospholipids (1,2,6). After secretion, bile acids enter the intestine, where they are metabolized by intestinal bacteria, deconjugated, and dehydroxylated. In this process, CA is converted to deoxycholic acid, and CDCA to lithocholic acid. Bile acids are reabsorbed in the terminal ileum and circulate via the portal vein to the liver. Here, they are reabsorbed, reconstituted, and resecreted into bile via the enterohepatic circulation.

## 3 Phospholipids

Phospholipids in bile are believed to be derived from membranous structures within the hepatocyte, such as the endoplasmic reticulum or lysosomes, or from the hepatocyte canalicular membrane. Over 95% of the phospholipids are phosphatidylcholines. Phospholipids are amphiphilic molecules and, similarly to bile acids, can solubilize and transport cholesterol. It is believed that phospholipid is translocated across the canalicular lipid bilayer by a protein similar to the multidrug resistance gene protein (7,8). Cholesterol and phospholipids then aggregate and are secreted into bile as vesicles. The secretory pathway of phospholipid and cholesterol is independent of that of the bile acid transporter pathway. However, vesicular secretion is quantitatively driven by bile acid secretion (1,2).

## 4 Proteins

Protein composes <5% of biliary solids. Proteins in bile are derived from plasma, the hepatocyte, and biliary ductular epithelium. Most biliary proteins, such as albumin,  $\alpha_2$ -macroglobulin, and IgG, are derived from plasma, but are present in bile in much lower concentrations. These proteins may enter bile by simple diffusion from the plasma compartment through hepatocyte tight junctions or through the epithelium of periductular capillaries. Other proteins, such as apolipoproteins, secretory IgA, or the hemoglobin-haptoglobin complex, are actively secreted into bile following nonspecific or receptor-mediated vesicular transport through the hepatocyte. The gallbladder adds to biliary proteins by secreting mucin, immunoglobulins, and other glycoproteins, which may have an important role in promoting gallstone formation (6,9).

## B Physical Chemistry of Biliary Lipids

Cholesterol is a hydrophobic molecule. To be transported in an aqueous environment such as bile, it must be solubilized by amphiphilic molecules such as bile acids or phospholipids. Cholesterol is transported in two forms, micellar and nonmicellar (vesicular), in bile (8,10). The thermodynamic stability of these two forms of transport differs. Since only a limited amount of cholesterol can be solubilized by bile acids and phospholipids, the relative concentrations of cholesterol, phospholipid, and bile acids determine in part the gallstone-forming capability, or lithogenicity, of bile. Lithogenicity is expressed as the cholesterol saturation index (11,12). Bile with a cholesterol saturation index greater than one is, by definition, supersaturated. Bile supersaturation is a prerequisite for cholesterol gallstone formation.

### 1 Nonmicellar Cholesterol Transport

Biliary cholesterol transport can be transported in unilamellar vesicles, which are 40–70 nm in diameter and consist of a bilayer of phospholipids interdigitated with cholesterol (3,13–17). Vesicles contain very little or no bile acids. In bile with a higher concentration of bile acids, such as gallbladder bile, these vesicles may fuse and form larger, multilamellar vesicles up to 500–1000 nm in diameter (15–17). Vesicles are believed to be less thermodynamically stable than mixed micelles, and cholesterol in these vesicles may coalesce to form a metastable state (3,13,18–20). Cholesterol in vesicles is felt to be more prone to nucleate and precipitate (20–23), and gallstone patients may have a larger proportion of cholesterol transported in this form (22).

## 2 Micellar Cholesterol Transport

Cholesterol is also transported in mixed micelles, which have diameters of 4–8 nm (1). Cholesterol can undergo dynamic exchange between the nonmicellar and micellar forms of transport (24,25), but only the micellar form is considered thermodynamically stable. Cholesterol equilibration between nonmicellar and micellar forms starts immediately after secretion. Transfer of both cholesterol and phospholipids from the nonmicellar to the micellar fraction is facilitated by increasing bile acid concentrations, as may occur with gallbladder stasis.

During this phase of “micellation,” more phospholipid than cholesterol is transferred to the forming micelle (1). The residual vesicles are thus less stable due to higher cholesterol-to-phospholipid ratio. However, with lower rates of bile acid secretion, the relative concentration of bile acids is too low to solubilize all biliary cholesterol, and therefore most cholesterol is transported in vesicular, less stable form (21). Under these circumstances, cholesterol crystals may form.

## C Role of the Gallbladder

Cholesterol gallstones occur very rarely in patients who have undergone previous cholecystectomy. Therefore, the gallbladder is believed to play an important role in gallstone formation. The gallbladder has storage, concentrative, absorptive, secretory, and contractile properties that may contribute to development of gallstones.

### 1 Motor Function

Gallbladder motility is commonly assessed by measuring fasting volume, contracted or residual volume, and fractional emptying. Maximal contraction is seen after meals. Between meals, the gallbladder may undergo partial emptying and filling. During periods of fasting, gallbladder contraction is weak, and bile accumulates in the gallbladder, with sequestration of the circulating bile acid pool. With the resulting fall in bile acid secretion rates, bile becomes progressively more saturated, and cholesterol crystallization or stone formation may occur. Contractile function of the gallbladder is important to empty any saturated bile, sludge, or small stones before larger stones can form (26). Gallbladder contractility is controlled through the endocrine and nervous systems. The most important hormone regulating gallbladder contractility is cholecystokinin (CCK). This hormone is released by the duodenum after meals, and causes gallbladder contraction and sphincter of Oddi relaxation (26). Neural control is mediated through both the vagus nerve and the sympathetic nervous system. Vagal activity enhances gallbladder contrac-

tion, while the role of sympathetic innervation is generally inhibitory (26).

Abnormal gallbladder motility, such as increased fasting volume and decreased fractional emptying, has been noted in animals and in a subgroup of patients who form sludge and gallstones (27–34). Some studies also show a slower rate of contraction after a fatty meal in gallstones patients (29). In many conditions that predispose to sludge or gallstone formation, gallbladder emptying is markedly inhibited owing to endocrine or neurologic abnormalities (26). For example, patients who are fasting or receiving total parenteral nutrition will have markedly diminished CCK release and gallbladder hypomotility (35,36). Treatment with the CCK antagonist somatostatin, as in patients with acromegaly, can inhibit gallbladder contractility (37,38). The obese, who are also predisposed to sludge and stone formation, may have diminished responsiveness of the gallbladder wall to CCK (33).

### 2 Mucosal Function

The gallbladder is generally thought of as a storage organ. However, several recent studies have demonstrated that the gallbladder can concentrate bile and alter its composition. The gallbladder epithelium acidifies bile, actively transports sodium and chloride, and absorbs water by passive osmosis. During this process, initially dilute hepatic bile is concentrated, leading to higher concentrations of biliary lipids, predisposing to cholesterol crystal nucleation. Bile pH and carbonate concentration decrease (39–42). Nucleation times also become more rapid with bile concentration (43).

In addition to its concentrative and absorptive functions, gallbladder epithelium secretes mucin glycoprotein (13). Mucin glycoprotein has extensive hydrophobic domains that can bind biliary lipids. In more concentrated bile, vesicles and micelles are entrapped in these binding sites and come into close and prolonged contact (44–48). Mucin hypersecretion has been shown to precede gallstone formation in prairie dog models, and probably entraps cholesterol within its hydrophobic domains (48–50). The stimulus for mucin hypersecretion is not entirely clear, but may be lithogenic bile, hydrophobic bile salts, prostaglandins, or arachidonic acid (49–51).

### 3 Nucleation of Cholesterol Crystals

Cholesterol crystal nucleation is the first step in gallstone formation. Nucleation begins with aggregation and fusion of unilamellar vesicles to multilamellar vesicles, with subsequent aggregation of cholesterol molecules to form crystals. This initial aggregation is

mediated at least in part by mucin binding of these lipids. Cholesterol that precipitates is derived primarily from biliary vesicles and precipitates using mucin glycoprotein as a nidus (20,44,52,53). Calcium ions are believed to be important in gallstone formation, as they can promote fusion of phospholipid-cholesterol vesicles. Calcium salts can also serve as a nidus for cholesterol precipitation and are usually found in the central core of cholesterol stones (2). Proteins, including albumin and other calcium-binding proteins, are found in the matrix of cholesterol stones, and thus may also serve as sites for nucleation (52,54,55). When cholesterol crystals reach a certain critical size, gallstone formation can occur with further deposition of cholesterol on the surface of the aggregate.

Normal biliary proteins can have pro-nucleating (56–62) and antinucleating (63,64) properties. Proteins with pro-nucleating properties include IgG, haptoglobin, phospholipase C, and aminopeptidase N (56–62). Proteins with antinucleating properties include apolipoprotein A-I and A-II (64), secretory IgA (65), and some small acidic glycoproteins (63). It is felt that these proteins somehow interact with and stabilize biliary lipids and calcium. The existence of proteins with antinucleating properties may explain the prolonged stability of bile that is supersaturated with cholesterol. The presence of proteins with pro-nucleating properties may contribute to nucleation, as high biliary protein concentrations have been found in supersaturated bile with cholesterol crystals (66). Many other, poorly characterized, nonmucin proteins are found in the core of cholesterol gallstones (52,54). The exact nature and role in the gallstone pathogenesis of these proteins is unknown.

#### 4 Growth of Cholesterol Crystals into Stones

Once a crystal of adequate size has formed, cholesterol, calcium bilirubinate, and other biliary lipids can deposit on its surface, leading to formation of visible gallstones. One study has suggested that bile in obese patients promotes more rapid crystal growth than in the non-obese (67). However, this process has not been as extensively studied as crystal nucleation, and little information is available on factors that may influence growth of stones.

### III EFFECTS OF OBESITY

Gallstone formation requires three conditions: secretion of supersaturated bile, nucleation of cholesterol crystals from supersaturated bile, and gallbladder stasis. Obes-

sity has direct effects on bile composition and gallbladder motility. This section will review the epidemiology of gallbladder disease and the effects of obesity on bile composition and gallbladder motility that predispose to gallstone formation.

#### A Epidemiology of Gallbladder Disease

Gallstones occur in populations throughout the world, but the prevalence varies substantially (68–71). In Western countries, the majority of gallstones are composed of cholesterol. Gallstones in the obese are composed primarily of cholesterol. The prevalence of gallstones in females varies from 3.7% in Indians and Pakistanis to 62.2% in Pima Indians (69,70). In males, the prevalence varies from 2.9% in Thailand to 25.9% in Pima Indians (70,71). Both racial and genetic factors likely contribute to the wide variation in prevalence. About two-thirds of patients with known gallstones do not have symptoms of biliary tract disease.

In all populations studied, the prevalence of gallstones increases with age (68–71). The prevalence of gallbladder disease increases markedly in those over 40 years old, such that 10–15% of Caucasian males and 20–40% of Caucasian females over the age of 60 have gallstones ultrasonographically. In the Pima Indians, a group known to have a high prevalence of gallstones, 68% of men and 90% of women over the age of 65 have gallbladder disease by oral cholecystography (70). With aging, biliary cholesterol secretion becomes excessive through mechanisms that are not well understood (72).

At all ages, females have a higher prevalence of gallstones than males, but in older age groups, the female predominance of gallstone incidence is less marked. Other states with higher estrogen stimulation, such as oral contraceptive use, higher parity, and estrogen replacement therapy, also are associated with greater risk of gallstones (73–75). Multiple theories have been put forth to explain this gender difference. Females may have a higher level of the enzyme 12 $\alpha$ -hydroxylase, with resulting higher biliary levels of CA and more supersaturated bile. Estrogens increase receptors for lipoproteins B and E, leading to increased hepatic cholesterol uptake (76). High levels of circulating estrogens have been shown to decrease the total bile acid and CDCA pools, with resulting increases in cholesterol saturation (77).

Risk factors other than ethnicity, age, and gender are less well defined and less well understood. Patients with diabetes mellitus or glucose intolerance have a higher incidence of gallstones in some but not all studies, likely secondary to altered gallbladder motil-

ity and hepatic lipid metabolism (78–81). A weak negative association between total serum cholesterol or LDL levels and gallstone formation has been seen in some but not all studies (73,74,79,82–84). Gallstone patients have mean triglyceride levels 21–26% higher and HDL cholesterol levels 14–19% lower than matched control patients (73,82–84). There is no clear consensus on the effect of alcohol consumption, smoking, or occupation on the risk of gallbladder disease (76,79,85,86).

Dietary factors have been implicated in gallbladder disease, but there are no clear data on the potential effects or mechanisms. Evidence exists that higher total caloric intake correlates with cholesterol gallstone formation. In the Nurses' Health Study, a significant trend toward higher risk of gallstones was seen with increasing caloric intake (86). However, in a study of Japanese-American men, there was an inverse correlation between total caloric intake and gallstone incidence (85). Studies differ in respect to the roles of total dietary fat, protein, or carbohydrate intake (87–89).

More recently, physical activity has been implicated has been implicated as a risk factor for symptomatic gallstones and cholecystectomy, independently of its effect on overall body mass index and weight loss (89–91). These studies, performed in both men and women, have shown that even moderate levels of recreational physical activity are protective against symptomatic gallstones. The mechanisms behind this phenomenon are unclear, although some have postulated that the effects of exercise on glucose tolerance, insulin levels,

and serum lipid levels may be responsible. Recent studies have found no effect of exercise on gallbladder contractility in obese women (92).

## B Risk of Gallstones in the Obese

Many studies have shown that obese women are predisposed to gallbladder disease (Table 1). The incidence of gallstones in obese women has been estimated at 2.6 per 100 person-years, with approximately two-thirds of these stones being asymptomatic (95). The relative risk seems to increase as body weight increases (73,74,78,85,86,93,96–99). Thus, the risk of gallstones relative to nonobese women is increased two times in women with a body mass index (BMI)  $>30$  kg/m<sup>2</sup> and seven times in women with a BMI  $>45$  kg/m<sup>2</sup> (86). However, there is not a defined threshold effect, as the relative risk of gallstones increases with BMI, even in women with a BMI  $<25$  kg/m<sup>2</sup>. Obesity seems to confer a greater relative risk in younger populations (98,100,101). In one study of obese adolescents, 55% of adolescent females undergoing cholecystectomy were obese, compared to 23% of adolescent females undergoing nongallbladder surgery, a relative risk of 4.2 (101). This relationship between obesity and gallstones is less striking in men, but several studies have also shown an increased risk of gallstones in men with increasing BMI (79,99,102,103). Up to 43% of men and women undergoing bariatric surgery have gallbladder disease, defined as prior cholecystectomy or gallstones (104,105).

**Table 1** Relative Risk of Gallstones with Obesity in Various Populations

| Reference | Study population                 | Diagnostic criteria                            | Normal population | Obese population | Relative risk |
|-----------|----------------------------------|--|-------------------|------------------|---------------|
| 78        | Japanese men age 48–56           | Screening by US                                | BMI $<22.5$       | BMI $>25$        | 1.9           |
| 85        | Japanese-American men            | Screening by US                                | BMI $<21.65$      | BMI 21.6–23.8    | 1.1           |
|           |                                  |  |                   | BMI 23.8–25.8    | 1.4           |
|           |                                  |  |                   | BMI $>25.8$      | 1.8           |
| 86        | Nurses' Health Study             | Previous cholecystectomy or symptoms           | BMI $<24$         | BMI 30–35        | 3.69          |
|           |                                  |  |                   | BMI 35–40        | 4.72          |
|           |                                  |  |                   | BMI 40–45        | 5.11          |
|           |                                  |  |                   | BMI $>45$        | 7.36          |
| 93        | Nurses' Health Study             | US if symptomatic                              | BMI $<22$         | BMI 22–24.9      | 1.6           |
|           |                                  |  |                   | BMI 25–31.9      | 3.3           |
|           |                                  |  |                   | BMI $>32$        | 6.3           |
| 94        | Obese prior to bariatric surgery | Previous cholecystectomy and intraoperative US | BMI $<20$         | BMI 35–40        | 5             |
|           |                                  |  |                   | BMI 40–50        | 7             |
|           |                                  |  |                   | BMI 50–60        | 8             |

US, ultrasound.

In addition to the effects of overall obesity, central or truncal adiposity is also correlated with the risk of gallstones in both men and women. In the San Antonio Heart Study of Mexican-American women, the risk for developing gallstone disease was 30% higher for women in the highest quartile of subscapular-triceps skinfold thickness ratio when compared to those in the lowest quartile (106). In a study limited to obese white women, Hartz et al. found the risk of gallbladder disease to be 75% higher in women in the highest quartile of waist-hip circumference ratio compared with those in the lowest quartile (107). Truncal skinfold thickness ratio has been correlated with later symptomatic gallstone formation in men, with men in the highest quartile having risk 2.5 times greater than men in the lowest quartile. This association was not altered after adjusting for initial BMI (108). In support of these findings, the lithogenic index of bile positively correlates with total body fat mass and intra-abdominal fat mass (109).

### C Alterations in Serum Lipids

Excessive body weight is associated with increased daily cholesterol synthesis and a larger pool of metabolically active cholesterol in the body. In addition, hepatic conversion of cholesterol into bile acids is impaired in the obese. The obese therefore have dual mechanisms contributing to the higher total cholesterol pool: increased synthesis and decreased degradation (110–112). There are also changes in lipid concentrations in serum, with decreased HDL cholesterol and higher LDL cholesterol levels. In the obese, serum triglycerides are elevated owing to excess hepatic synthesis of VLDL and triglycerides, an effect of peripheral hyperinsulinemia and enhanced peripheral lipolysis. Lower lipoprotein lipase activity leads to decreased triglyceride clearance (113). As discussed previously, gallstone formation has also been correlated with higher serum triglyceride and lower serum HDL levels. However, it is not clear if altered serum lipids are a direct cause of gallstones, or if both disorders are a reflection of an underlying common metabolic derangement.

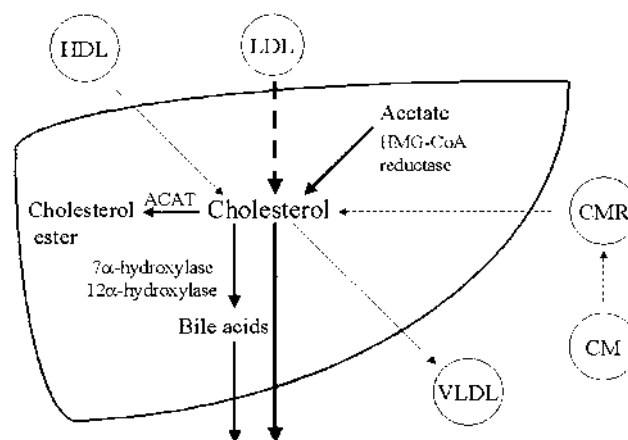

### D Alterations in Bile Composition

Overall, biliary cholesterol secretion is increased in the obese relative to the nonobese with or without gallstones. However, when normalized to subject weight, cholesterol secretion appears normal in obese patients without gallstones. In contrast, in obese patients with gallstones, cholesterol secretion is markedly elevated,

even after correction for body weight (114–119). This marked cholesterol hypersecretion, with a resulting higher cholesterol saturation index, is felt to be the primary mechanism predisposing to gallbladder disease in the obese (115–119).

The pathophysiology of cholesterol hypersecretion in the obese is poorly understood. Putative mechanisms of cholesterol hypersecretion include increased cholesterol uptake from lipoproteins (76), increased cholesterol synthesis by HMG CoA reductase (112,120), decreased cholesterol catabolism by cholesterol 7 $\alpha$ -hydroxylase (120,121), and decreased esterification of cholesterol within the hepatocyte (112). It seems likely that cholesterol hypersecretion is secondary to a combination of these effects. Recent data suggest that leptin may be a molecular mediator of cholesterol hypersecretion (4) (Fig. 1).

In contrast to the consistent data showing cholesterol hypersecretion, the data on alterations in bile acid secretion are variable. The total pool and biliary secretion of bile acids are felt to be normal to increased in the obese. However, when normalized for body weight, bile acid secretion is lower than in the non-obese, and the relative percentage of bile acids is lower owing to the marked increase in cholesterol secretion (116–118,122–124). The data on phospholipid secre-

**Figure 1** Hepatic cholesterol metabolism. In the liver, cholesterol may be derived from circulating lipid particles or synthesized de novo from acetate via the HMG CoA reductase pathway. Export pathways of cholesterol include incorporation into circulating VLDL particles, esterification via the ACAT enzyme, conversion to bile acids, or secretion into bile. LDL = low-density lipoprotein; HDL = high density lipoprotein; CM = chylomicron; CMR = chylomicron receptor; VLDL = very low density lipoprotein; ACAT = acetyl CoA cholesterol acyl transferase.

tion are also variable, with different studies showing unchanged to elevated total phospholipid secretion (115–118). Evidence also conflicts on the relative percentage of biliary phospholipids. No change in the relative composition of biliary phospholipids is found with obesity (116).

From the previous evidence, it follows that markedly increased cholesterol secretion in the obese, coupled with an unchanged to mildly increased bile acid secretion, leads to an increase in the cholesterol/bile salt ratio (124). Cholesterol saturation index thus increases with BMI, independent of age, gender, or ethnicity (124). As a correlate, bile becomes more lithogenic. In contrast to nonobese individuals, where bile is supersaturated only with fasting, supersaturation of bile is not transient, but persists even after feeding. The obese thus have more supersaturated bile that persists for longer periods of time.

### E Alterations in Gallbladder Motility

Gallbladder stasis is an important factor that predisposes to formation of gallstones. Obesity in itself is associated with gallbladder hypomotility and stasis, with many studies showing increased fasting volumes, increased residual volumes, and decreased fractional emptying (30–32,125,126). Multiple mechanisms may predispose to alterations in gallbladder motility in the obese. Alterations in peripheral CCK levels have been

postulated, but not yet proven. Diminished gallbladder responsiveness to CCK has also been proposed (126). Another proposed mechanism is related to accelerated gastric emptying. Rapid emptying of a meal would diminish the amount of time that food or chyme is in the duodenum. There would then be a resulting decrease in release of CCK, with lesser stimulation of gallbladder emptying (32).

## IV EFFECTS OF WEIGHT LOSS

Obesity itself is associated with a marked increase in the incidence of gallbladder disease. Paradoxically, weight loss, through either dieting or bariatric surgery, is also associated with a further increase in the incidence of gallstone formation (Table 2). This section will review the incidence, pathophysiology, and prevention of gallstone formation during weight loss.

### A Incidence of and Risk Factors for Gallstone Formation

#### 1 Incidence

In follow-up of the Nurses' Health study, women losing 4–10 kg had a 44% increase, and those losing >10 kg had a 94% increase in the risk of gallstones (93). Interestingly, the risk of symptomatic gallstones in this population was also influenced by long-term weight

**Table 2** Risk of Gallstone Formation with Weight Reduction

| Reference | Study population                   | Method of weight loss | Diagnostic test     | Follow-up period                   | Percent with gallstones |

US, ultrasound.

patterns (136). Women whose weight fluctuated and women with net weight loss over time had higher prevalence of gallstones than those who maintained a steady weight.

The overall incidence of gallstones ranges up to 25% in the 8–16 weeks after initiating a weight reduction diet (127–130,137). It has been suggested that the risk of gallstone formation increases dramatically if the rate of weight loss exceeds 1.5 kg per week (138). In addition, the composition of the weight loss diet, especially the amount of fat included, may be important. Patients given a diet containing >10 g fat per day are at lower risk of gallstone formation than those who consume <10 g fat per day, perhaps due to maintenance of gallbladder motility (139–142).

Patients losing weight with either low-calorie diets or bariatric surgery seem to be at risk (143). One study has shown a 37% incidence of gallstones 6 months after bariatric surgery. A high percentage of patients will also develop biliary sludge in the first postoperative year (131). The risk for gallstone formation is greatest in the first postoperative year, but may be increased for up to 3 years postoperatively, as weight loss continues. Although these periods are coincident with the periods of greatest weight loss and ongoing weight loss, respectively, the risk for gallstone formation does not necessarily correlate with the degree of weight loss. Twenty-four percent to 40% of those developing gallstones will be symptomatic, and ~28% may need repeat surgery for cholecystectomy (104,105, 131). Asymptomatic gallstones will resolve in about 50% after 1–2 years (144). Gallbladder concentrations of biliary lipids and cholesterol saturation index do not predict who will develop gallstones (94,128,132, 143,145,146).

## 2 Risk Factors

Both initial BMI and the relative rate of weight loss are predictors of gallstone development (132). Absolute weight loss is more difficult to assess, as it is highly dependent on initial BMI (132). Likewise, the rapidity of weight loss has not been established as a definite risk factor owing to confounding with absolute and relative amounts of weight lost. Higher rates of gallstone formation during weight loss are seen in men. However, this effect is removed when controlling for the higher initial BMI, relative BMI lost, and initial serum triglycerides seen in obese men as compared with obese women (132). Diets in which gallbladder motility is maintained, such as diets with higher caloric or fat contents, do not seem to be associated with as great a

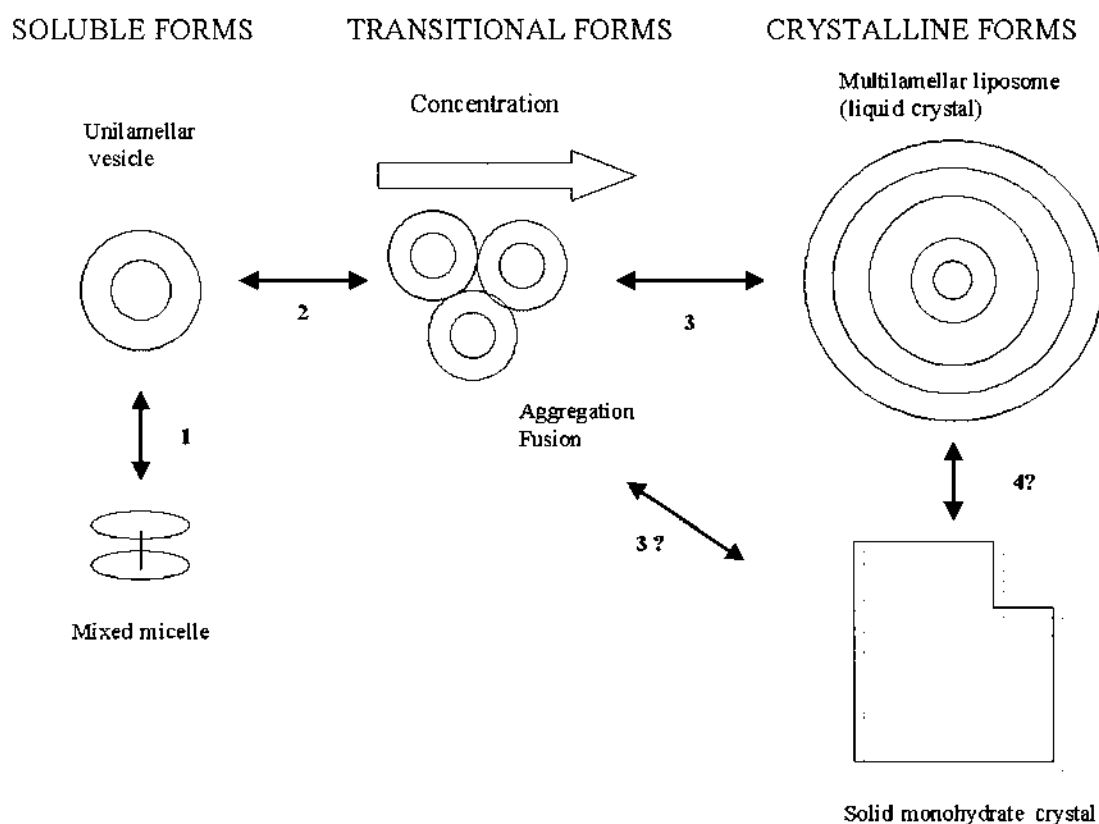

risk of gallstone formation (141,147). Repeated cycles of weight loss also seem to predispose to gallstone formation (136). No studies have looked at effects of weight loss due to increases in physical activity in relation to gallstone formation.

## B Pathophysiology of Gallstone Formation During Weight Loss

Changes in bile composition that lead to increased lithogenicity are seen with very low calorie diets. CSI in bile increases on average during weight reduction (134,137,139,141,148–151). However, this effect is not seen in all subjects studied; some patients have large increases, and others have large decreases in saturation index. CSI and nucleation time decrease in nearly all patients after a prolonged fast. It is felt that hepatic cholesterol secretion increases during weight loss and decreases again during weight maintenance. Similarly, the molar percentage of cholesterol increases during the weight loss phase and decreases in the weight maintenance phase (131,134,148–151). The excess excreted cholesterol during weight loss is mobilized from peripheral adipose tissue. Counteracting these factors is the fact that low caloric intake lowers cholesterol input and may reduce bile acid secretion and cholesterol synthesis. Biliary cholesterol secretion will reflect a balance of all these variables. In the weight stabilization phase after a low-calorie diet, CSI decreases to below the baseline value. Nucleation time decreases concurrently with these changes (150) (Fig. 2).

Bile acid and phospholipid secretion do not reliably change with weight loss, but generally are lower (122, 134,151,152). The total bile acid pool decreases during weight reduction, but the individual bile acid profile does not change (122). If patients regain weight, the cholesterol saturation index and molar percentage of cholesterol will again increase (153). In weight loss induced after jejunoileal bypass, similar changes in bile composition and lithogenicity are noted. Bile salt pool is initially reduced, and saturation index is increased. However, bile composition reverts to normal by about one year postoperatively (150,151).

Gallbladder motility changes with weight reduction. Decreases in gallbladder motility are seen after major abdominal surgery. With gastric bypass, gallbladder hypomotility may be induced because of intraoperative transection of the vagus nerve (32,141,143,146,154). Many of the changes in bile composition during weight loss could be a reflection of this gallbladder stasis, rather than a direct result of alterations in hepatic secretion or

**Figure 2** Schematic of cholesterol nucleation. In bile, cholesterol exists in two soluble forms—vesicles and mixed micelles. They are in dynamic equilibrium (1), depending on total bile salt concentration and lipid density. With concentration, the vesicles may be depleted with phospholipid and enriched with cholesterol, resulting in a tendency for the vesicles to aggregate and fuse (2). Pro-nucleators may aid vesicular fusion. The fused vesicles are transitional forms and lead to formation of multilamellar liposomes or liquid crystals (3). Cholesterol separates from the liquid to solid crystalline forms during nucleation (4). It is unclear whether fused vesicles can nucleate into solid cholesterol crystals. (From Ref. 168.)

gallbladder mucosal function. With very low calorie diets, increased fasting and residual gallbladder volumes can be seen (155). This effect may be reversed by inclusion of adequate calories (> 800 kcal/d) or dietary fat (> 10 g/d) to maximally stimulate gallbladder contractility (139,140,147,155).

## C Prevention

### 1 Screening for Gallstones Prior to Weight Reduction

Patients undergoing bariatric surgery are often screened with preoperative ultrasound to determine the need for concomitant cholecystectomy. However, preoperative ultrasound has a low sensitivity for gallbladder disease in the obese, and may not be the best test to determine need for cholecystectomy. Some have advocated screen-

ing for gallbladder disease prior to weight reduction dieting and possibly dietary modification if gallstones are found. However, this approach has not been studied systematically (143). It is not known if patients with preexisting cholelithiasis are at higher risk of complications, such as acute cholecystitis or pancreatitis, with weight reduction.

### 2 Prophylactic Cholecystectomy

Some authors have advocated prophylactic cholecystectomy at the time of bariatric surgery because of the >30% incidence of gallstones in the initial period of rapid weight loss. From 10% to 25% of patients who have not had a prior cholecystectomy will already have gallstones at the time of surgery, and 95% of patients undergoing cholecystectomy at bariatric surgery will have pathologic evidence of gallbladder disease (104,

105). Cholecystectomy adds only minimally to procedure time (30–45 min), and patients undergoing prophylactic cholecystectomy have not had a higher incidence of perioperative complications or a longer hospital stay. Many centers have moved to routinely performing cholecystectomy at the time of gastric bypass surgery (104, 105). Prophylactic cholecystectomy before initiating weight reduction diets has not been advocated.

### 3 Bile Acid Supplementation During Weight Loss

Bile acid supplementation has been used as a nonsurgical treatment for gallstones. Certain bile acids, CDCA and ursodeoxycholic acid (UDCA), contribute to cholesterol solubilization and can decrease bile lithogenicity. Bile acid supplementation is generally well tolerated and without significant adverse effects.

In the nonobese, treatment with CDCA desaturates bile and prolongs nucleation times (20,156). However, this effect is not seen consistently in the obese, even with the same doses per kilogram being administered (17,18,157–160). Biliary cholesterol concentrations and saturation indices reliably decrease to unsaturated ranges only with high dose therapy (157–160). HMG CoA reductase activity is reduced during CDCA therapy, with subsequent reduction in hepatic cholesterol synthesis and secretion (122). However, CDCA is a potent inhibitor of cholesterol 7 $\alpha$ -hydroxylase, and thus decreases cholesterol catabolism. With oral therapy, this bile acid can increase the total bile acid pool and the rate of bile acid secretion, and in fact, becomes the predominant circulating bile acid. Although it has beneficial effects on bile composition, CDCA may increase gallbladder mucin secretion, and potentially enhance cholesterol crystal nucleation (49–51).

Currently, the use of UDCA has superseded that of CDCA. UDCA is safe and effective. Treatment with UDCA prolongs nucleation times and decreases the concentration of cholesterol and phospholipid present in the vesicular phase (20,135,157–161). Gallbladder bile from patients treated with UDCA contains only a trace of cholesterol in vesicles, the more lithogenic form of transport (162). Similar to CDCA, UDCA decreases biliary cholesterol concentration by decreasing activity of hepatic HMG CoA reductase (122). It has no effect on the activity of cholesterol 7 $\alpha$ -hydroxylase. The molar percentage of bile acids is unchanged to slightly increased with UDCA, and UDCA becomes the predominant bile acid during therapy (122,135,161). In addition to its effects on bile composition, UDCA may

be able to maintain gallbladder motility in patients losing weight (163). All these factors combined indicate that UDCA may have a role in prophylaxis or treatment of gallstones in the obese. Randomized, controlled studies showed that giving UDCA at 600 mg/d during weight reduction dieting (164) or after gastric bypass surgery (165) can significantly decrease the incidence of biliary sludge and gallstones. In addition, prophylactic use of UDCA has been estimated to be cost saving in patients on weight reduction diets or after gastric bypass surgery (166).

### 4 Other Pharmacologic Measures

One study looking at high-dose aspirin (1300 mg/d) showed that none of 22 patients receiving aspirin developed gallstones during a weight reduction diet. Three of these patients developed microstones or crystals (167). However, there was no change in the saturation index, cholesterol concentration, bile acid concentration, or biliary glycoprotein concentration. Other studies have shown a possible effect of nonsteroidal anti-inflammatory drugs in inhibiting gallstone recurrence in patients losing weight (163). Although mucin secretion and prostaglandin metabolism may be modified by nonsteroidal anti-inflammatory drugs, the long-term clinical use of these compounds can be associated with substantial complications. The feasibility of using aspirin or nonsteroidal anti-inflammatory drugs for this indication has not been clearly established.

## V SUMMARY

Gallstones are a common clinical problem in the obese and the nonobese. Three separate conditions are required for gallstone formation: secretion of supersaturated bile, nucleation of cholesterol crystals, and gallbladder stasis. In obesity, bile is more saturated owing to cholesterol hypersecretion, and gallbladder motor function is impaired, predisposing to gallstone formation. Recent research suggests that leptin may mediate the association between obesity and gallstones. Paradoxically, weight reduction either through dietary modification or through bariatric surgery also predisposes to gallstone formation. The mechanisms of gallstone formation during weight reduction are not entirely clear, but also involve altered bile composition and gallbladder motility. Ursodeoxycholic acid is the only medical therapy that has been studied for gallstones during weight reduction. Further research needs to be done into the risk factors for and treatment of

gallstone disease and its prevention in the obese and in those losing weight.

## Obesity and Pulmonary Function

**Shyam Subramanian and Kingman P. Strohl**

Case Western Reserve University School of Medicine, Cleveland, Ohio, U.S.A.

### I INTRODUCTION

The importance of this chapter lies in the fact that impairment of respiratory function by obesity is potentially reversible and therefore should be a focus for therapeutic intervention (1–12). This review will be composed of three parts. The first will be the description of changes in respiratory mechanics, gas exchange, and control with obesity such as physiological decrements that result in dyspnea, the increased work of breathing, and abnormalities in gas exchange that many obese individuals exhibit. The second part will include a discussion of pathophysiologic staging of respiratory impairment in obesity, using as a basis a classification system proposed by Bates (13). The third part will outline the emerging literature on sleep disordered breathing and obesity, obesity and asthma, and the syndrome of obesity hypoventilation.

### II PHYSIOLOGICAL DECREMENTS WITH OBESITY

#### A Respiratory Compliance and the Work of Breathing

A threshold effect of obesity associated with respiratory compromise has not been defined. While most studies in this literature use a starting point of at least 120% of ideal body weight (IBW), some use different thresholds for entry—150% or 200% IBW, BMI values >30

(males) or >28 (females). The literature is too heterogeneous to combine studies or to examine the relationship of obesity to respiratory function using continuous variables for each condition. Therefore, we will discuss studies that examined categorical effects (obese vs. non-obese subjects).

Respiratory compliance is a measure that relates to the pressure changes that are required to increase lung volume and can be influenced by the mechanical properties of both the lungs and the chest wall (14–16). One major problem in obesity is that increased weight pressing on the thoracic cage and abdomen makes the chest wall stiff and noncompliant (14,15). In addition to increased adiposity around the thoracic cage, chest wall compliance may be decreased because the decreased total thoracic and pulmonary volume may pull the chest wall below its resting level to a flatter portion of its pressure-volume curve. In a study on sedated, paralyzed, postoperative morbidly obese patients, functional residual capacity (FRC) was seen to be markedly low compared to normals, and respiratory compliance was found to be low owing to significant decrease in both lung and chest wall compliance (17).

Total respiratory system resistance was also markedly increased, primarily owing to an increase in lung resistance. Oxygenation was impaired and correlated with total respiratory system compliance. PaCO<sub>2</sub> was not different between obese and lean subjects and did not relate to compliance, resistance, or FRC. The same group later compared respiratory mechanics during

general anesthesia among groups of normals, overweight subjects, and obese subjects (BMI 25–40) and subjects with morbid obesity (BMI > 40) (18). Increasing BMI was correlated to an exponential increase in FRC. Compliance of both the total respiratory system and the lungs decreased; in contrast, the compliance of the chest wall was only minimally affected, and the resistance of the lung and of the total respiratory system increased. Chest wall compliance falls more in obese than lean subjects in moving from the sitting to the supine or even prone position (14,19). In obese patients, prone positioning has been shown to improve pulmonary function, by increasing FRC and lung compliance during general anesthesia (20).

There is a relationship between chest wall compliance and CO<sub>2</sub> retention, independent of body fat. In those obese individuals with an increase in arterial PaCO<sub>2</sub> and therefore alveolar hypoventilation, chest wall compliance was one-third of normal, whereas in equally obese but eucapnic subjects, chest wall compliance was in the normal range (16). The mechanism for the differences in chest wall compliance in the two groups was not studied; the interpretation of the results centered on the role of chest wall compliance in CO<sub>2</sub> retention.

The lung itself may be indirectly affected by chest wall mass loading, as lung compliance in addition to chest wall compliance is decreased in some obese individuals (14,21,22). Mechanisms for increased lung stiffness include a large pulmonary blood volume and/or dependent airways, greater collapse of alveolar units and/or intrinsic alterations of the elastic characteristics of lung tissues with surface lining film modifications. Another factor would be the imposition of abdominal fat, producing a cephalad-displaced diaphragm, and restricting lung inflation and promoting recoil in expiration. Experimental mass loading of the chest wall produces dependent bronchioalveolar units with atelectasis which increases further the work of breathing (23). With both an increased lung and chest wall stiffness, in an obese individual there is an increased mechanical work of breathing as well as an oxygen cost of breathing (24,25). Work of breathing can be increased two- to threefold even in obese eucapnic individuals. Another factor contributing to this increased work of breathing is the marked increase in lung and consequently respiratory resistance (18,26).

## B Abnormalities in Pulmonary Function Tests

While age and smoking play an important role in determining the rate of decline in the ventilatory capacity, it is clear that body weight is an important

risk factor and one that is to be considered both epidemiologically and clinically. Obesity produces a progressively restrictive ventilatory deficit that becomes more evident as BMI is elevated. There occur decreases in the functional residual capacity, the expiratory reserve volume, and total lung capacity (TLC) in those defined as obese (>120% of IBW) (13,15,27–31). Both the forced vital capacity (FVC) and the maximal ventilatory ventilation (MVV) are reduced proportional to the rise in body weight and the decrease in respiratory compliance (13,32–34). Longitudinal analyses have found that weight or BMI gain is associated with accelerated loss of ventilatory function (35,36). In a study on obese snorers with and without sleep apnea, a significant correlation was found between the severity of the apnea-hypopnea index and reductions in expiratory flow rates and specific airway conductance (26). The DLCO is not elevated (34). No differences have been observed in spirometry results in sitting or standing position (37). However, body weight and respiratory compliance appear to account for ~60–70% of the variance in values in obese individuals, indicating that other factors act to reduce FVC and MVV in this population. Body fat deposition may have distinct impacts on ventilatory function measures. A central pattern of adiposity is typically seen in obese men, and a high waist-to-hip ratio, seen in these subjects has been shown to be inversely correlated to spirometry and static lung volumes (38). It seems that the effect of a central pattern of fat distribution is modified by age, since it was seen only in observations from men within the ages of 40 and 59 years (39).

## C Gas Exchange and Respiratory Control

Obesity exerts an increased demand to maintain normal arterial PCO<sub>2</sub> and PO<sub>2</sub> levels. The work involved in moving increased body weight results in a larger CO<sub>2</sub> production for height in obese than in nonobese subjects; this effect is present during rest but is more evident with exercise (15,24,25). Obese subjects with increased respiratory system compliance also must work harder to eliminate CO<sub>2</sub> (40). Morbidly obese patients may be dedicating a disproportionately high percentage of total oxygen consumption to conduct respiratory work even during quiet breathing (41).

The majority of obese subjects exhibit an increased ventilatory drive and maintain a eucapnic state (14,27). The subset of patients with obesity-hypoventilation will be discussed in a separate section. In moderately and severely obese individuals (>190% to >200% of IBW), arterial blood gases often show hypoxemia due to a

widened alveolar-to-arterial (A-a) gradient (42). The increased A-a gradient arises from a mismatch of ventilation and perfusion, i.e., relating to increased relative perfusion at the lung basis where reduced ventilation occurs due to airway closure and alveolar collapse (42–46). Obese patients who have normal or slightly reduced CO<sub>2</sub> levels have either increased or normal ventilatory drive from hypoxic responses.

Two other factors may contribute to inefficiencies in gas exchange. Obese individuals achieve a minute ventilation with a relatively smaller tidal volume and increased frequency, and while this pattern reduces the work of breathing, it increases the dead space and decreases alveolar ventilation at any given minute ventilation of breathing (47). A second factor is that in severely obese subjects the diaphragm may be overstretched in the supine position (48). Overstretching is a consequence of the mechanical loading by abdominal contents and places the diaphragm at a mechanical disadvantage that contributes to decreased inspiratory strength in the supine posture (48). This factor may be particularly important during sleep when postural muscle tone is decreased (32).

#### D Dyspnea and Exercise

A common complaint in the obese individual is dyspnea, a sense of shortness of breath on exertion or at rest (49,50). In a recent study, 60% of patients with a BMI > 28 and no comorbid conditions reported some dyspnea at rest (51). Factors that appear to correlate with increased shortness of breath include the decrease in chest wall compliance and the inefficiency of the respiratory control system (see above). The moderately obese individual, though, can sustain a level of ventilation to maintain normal levels of arterial PCO<sub>2</sub> and increase ventilation appropriately with exercise (52). This indicates that the metaboreceptor response to exercise can be intact, at least in moderately obese individuals.

There are three somewhat unique aspects of exercise related to obesity. The first relates to the increased ventilatory demands imposed by the increased weight of the individual. This effect is seen clearly in that ventilation for a given work load on treadmill testing is much greater than that on bicycle testing (15,52–54) and is explained by the weight borne while walking. A second effect relates to the observation that while ventilation is usually increased in relationship to oxygen consumption, in the moderately obese subject studied both at rest and with exercise, arterial oxygen levels increase on exercise with little change in PaO<sub>2</sub>. This response is attributed to improved ventilation-perfusion matching

(52), indicating that gas exchange abnormalities at rest are functional rather than structural. A third factor is the mechanical constraint on end-expiratory lung volume before and after exercise (55). The lower end-expiratory lung volume during resting breathing in the obese subject is principally due to changes in mechanical properties of the chest wall. Even in simple obesity the pressure-volume curve, while displaced, is linear above end-expiratory lung volume but, unlike normal subjects, very nonlinear below FRC (27). Furthermore, in contrast to lean individuals, obese individuals do not decrease their end-expiratory lung volume during exercise (56). Mechanisms have not been extensively studied. However, it may be that the reduction in chest wall compliance makes the chest wall harder to displace inward or that, below FRC; expiratory muscles operate more inefficiently in expiration in the obese individual. The consequence of a failure to reduce end-expiratory lung volume during exercise is a failure to place the diaphragm at a better mechanical advantage, as well as an inefficient partitioning of the work of breathing between the inspiratory and expiratory muscles (55). An impaired exercise response is seen even in mildly obese individuals and may explain dyspnea on exertion even in those with normal spirometry or gas exchange.

In summary, the metabolic consequences of obesity combined with abnormalities in motor outflow and muscle dysfunction contribute to the respiratory complaints at rest and to exercise intolerance. What is not known is how these develop over time and whether or not certain individuals are predisposed to abnormalities because of factors independent of the level of obesity or factors present as a consequence of the metabolic and cardiovascular syndromes associated with obesity.

### III CATEGORIES OF RESPIRATORY COMPROMISE IN OBESITY

Bates (13) proposed that the respiratory effects of obesity be classified into three stages relating to the magnitude of obesity and clinical illness associated with obesity (see Table 1). This staging of dysfunction may have been derived from efforts to classify cardiovascular morbidity from obesity (12). We see a staging scheme as an arbitrary but convenient starting point to discuss the influence that obesity can have on respiratory pathophysiology and illness. What should be emphasized at the onset is that such a classification system serves merely to organize thinking about obesity and its effects on respiratory function and pathophysiology. Individuals will not fall neatly into each category, and the

**Table 1** Classification of Obesity-Related<sup>a</sup> Respiratory Compromise

---

|   |
|---|
| Stage I: Weight-to-height ratio <sup>b</sup> <1, normal FVC and FEV1, reduction in end-expiratory reserve volume, PaCO <sub>2</sub> at the lower limit of normal (36–40 mmHg), decrements in exercise capacity related to weight and reserve volumes, independent of conditioning.  |
| Stage II: Weight-to-height ratio >1, impairments in lung volumes, dyspnea at exercise and at rest, increased A-a gradient, decrements in function in the supine posture, normal PaCO <sub>2</sub> (40–45 mmHg) or mild hypercapnia at rest may indicate sleep-disordered breathing. |
| Stage III: Stage II compromise in the presence of illness: pulmonary hypertension and right heart failure, obesity-hypoventilation syndrome, obstructive sleep apnea syndrome, and morbid obesity syndrome.   |

health outcome effects of an initial classification of individuals are not known with the possible exception of those with morbid obesity. Also, despite its common use in study criteria, we suspect that the distinction among mild, moderate, and severe consequences of obesity may not have, as a defining trait, a numerical value for obesity, expressed as a percent of IBW or BMI. Rather, illness is the result of interaction between sites of fat deposition, time of exposure to obesity, and other inherited or acquired traits of respiratory function or comorbid conditions such as aging or cardiovascular disease.

Patients classified as stage I (Table 1) include those who are mildly obese with a ratio of weight to height (kilograms over centimeters) <1 and body weight of ~120% of IBW. In many of these individuals lung mechanics are usually normal, airway resistance is normal, and the subdivisions of lung volume show only a small reduction in expiratory reserve (17). Arterial blood gases are usually normal at rest. Abnormalities in gas exchange may occur during sleep due to the mechanical effects of chest wall loading in interaction with the reduction in postural tone in muscles of the upper airway and chest wall. Exercise tolerance may be reduced by inactivity and/or by a failure to reduce end-expiratory lung volume. Recumbency results in inefficiencies in ventilation, in vascular perfusion, and in diaphragm function.

In stage II, patients are more severely obese with a ratio of weight to height of more than stage I; these individuals are generally >150% of ideal body weight. In these individuals there are decreases in lung as well as chest wall compliance and hypoxemia due to an increasing A-a gradient. These changes are due to ventilation-perfusion mismatching. Gas exchange abnormalities can be reversed, and PaO<sub>2</sub> and oxygen saturation will increase after deep breaths. There is a restrictive defect with FVC and TLC <80% of predicted, and the ratio of FRC to TLC falls to ~25%. In patients with moderate

obesity there is a steady decline in ventilation-perfusion ratio from apex to base in the upright posture, and airway closure is further enhanced in the supine posture. Polycythemia may be present, and more severe blood gas changes can be demonstrated during sleep due to ventilation/perfusion mismatch. In this group of patients (stage II), respiratory frequency is increased at rest, tidal volume decreased, and the respiratory drive increased with an increased response to hypoxia but a decreased response to hypercapnia. The ventilatory response to exercise can be normal even in those whose hypercapnic response is depressed. Gas exchange during sleep is impaired by increased closure of lung units and by impairment of muscle function. Apneas during sleep are increased (57), and hypercapnia may occur during sleep secondary to hypoventilation. The presence of hypercapnia during the day may be a consequence of sleep-disordered breathing (58) or coexisting illness (3) or upper-airway obstruction (59). However, sleep-disordered breathing is not accompanied by signs and symptoms of illness during the day; the degree of sleepiness resulting from sleep fragmentation is similar to that in the general population (10). In this group of patients, weight loss achieved either through behavioral modification or through jejunoileal bypass can result in improvement in all these physiological abnormalities (9,11,29,33,60). But it must be noted that many of these good results were reported for younger subjects with moderate obesity. Respiratory complications of surgery for weight loss occur more commonly in older individuals, those who are hypercapnic (perhaps as a result of sleep-disordered breathing), and those who seem to have a reduced expiratory reserve volume prior to surgery (13,32). This impression should be confirmed in longitudinal and prospective studies of outcome assessment.

Stage III or illness-defined obesity impairment includes morbid obesity with edema and cor pulmonale, the obesity-hypoventilation syndrome, and sleep apnea

syndrome (both reviewed below). Patients in this category exhibit an inherent predisposition to pulmonary embolism (61,62). Pulmonary hypertension, which can be present in these patients during light exercise, may predispose these patients to inactivity, to dependent edema, and to subsequent risk for venous thrombosis (61). The effects of pulmonary emboli on the lung of an obese individual will be compounded by abnormalities in respiratory function imposed by increased weight alone (62) (see section on OHS). Another confounding factor in this classification is the relationship of respiratory morbidity to the circulatory physiology and pathophysiology of obesity (61,63).

#### IV SLEEP-DISORDERED BREATHING AND OBESITY

Obstructive sleep apnea (OSA) syndrome is characterized by loud snoring, episodic partial or complete obstruction of the upper airway during sleep, and consequent sleep fragmentation leading to excessive daytime sleepiness. In addition to the morbidity associated with chronic sleepiness, patients with OSA are at increased risk for hypertension, myocardial infarction, and stroke (10). The diagnosis and treatment of OSA have been reviewed elsewhere (10,64–66), although a few key points are mentioned here. When OSA is suspected clinically, the diagnosis is conventionally confirmed via polysomnography, a test in which multiple physiological variables including the electroencephalogram, electrocardiogram, and several measures of respiratory function are recorded during sleep. The most common measure of OSA severity determined in this manner is the total number of apneas (cessation of airflow of 10 sec) and hypopneas (partial obstructions) per hour of sleep (apnea + hypopnea index; AHI). However, other features in the presentation may indicate the need for a therapeutic intervention.

Population studies in the United States and several other countries suggest that the syndrome of obstructive sleep apnea, daytime sleepiness, and cardiovascular disease is present in ~1–4% of working men and women (10,67). There are pockets of higher prevalence, for instance in minority populations and children with tonsillar hypertrophy; however, one of the best-characterized associations is between obesity and OSA. The correlation between body weight and sleep apnea was so strong as to dominate recognition strategies for almost two decades and link sleep apnea almost exclusively with obesity hypoventilation or Pickwickian syndrome (64,66,68); however, in community studies the associa-

tion of OSA with obesity is not as strong as in clinic-based case collections or reviews from referral centers (10,68). A brief review of this association follows, as does a more thorough account of the literature regarding mechanisms and the effect of weight reduction.

##### A Association Between Obesity and OSA

In clinical rather than community populations, many are at least 130% of ideal body weight (10), and obesity (expressed as BMI in  $\text{kg/m}^2$ ) is the strongest predictor of AHI in subjects over age 50. Compared to the other factors studied, BMI was twice as strong as gender, and fourfold stronger than age, in predicting AHI, even when subjects with the most severe disease ( $\text{AHI} > 60$ ) were excluded from analysis (69). In a polysomnographic study of 250 obese patients without sleep complaints, only 40% of the men and 3% of the women were found to have sleep apnea severe enough to warrant treatment (70).

The recent population-based study of Wisconsin state employees supports the findings of these clinic-based reports (67). In this cohort of >600 men and women between 30 and 60 years of age, an increase in BMI of 1 SD was associated with a fourfold increase in risk for OSA (defined as an  $\text{AHI} > 5/\text{hr}$ ). More recently, the same group reported that a weight gain of as little as 10% predicted a sixfold increase in the odds of developing moderate to severe sleep-disordered breathing. Conversely, a loss of 10% of body weight predicted a 26% decrease in the apnea-hypopnea index (71). After examining several measures of body composition and metrics related to fat deposition, neck circumference was the strongest predictor of AHI although all anthropomorphic variables were highly correlated. These and other observations suggest that an upper-body fat deposition profile, rather than a more generalized distribution of body fat, may be important for the development of sleep apnea. Given the strength of the association, defining the causal relationship between excess body weight and OSA remains surprisingly difficult. Studies of mechanisms can be grouped into one or more categories based on hypotheses involving alterations in upper-airway (UA) structure. The major theory is that obesity leads to a change in UA structure or function or alteration in respiratory drive, particularly to muscles regulating nasopharyngeal and oropharyngeal patency. Obesity even in the absence of sleep-disordered breathing can be associated with excessive daytime sleepiness (72). The same study also found that obese patients tend to underestimate their degree of sleepiness. So the recognition profiles designed to detect sleep-disordered

breathing that involves sleepiness may not be as specific for OSAHS as it might be in a nonobese individual.

## B Obesity and Upper-Airway Function

The major theory is that obesity leads to a change in the UA geometry, either through loading of the pharyngeal wall or by encroachment from periluminal fat deposits, placing it at increased risk of collapse due to physical forces acting on the pharyngeal segment during inspiration. Imaging studies indicate that obese patients with OSA have significant narrowing of the UA compared with nonobese controls while awake using computed tomography (73–75). These studies have demonstrated significant differences in cross-sectional area at naso-, oro-, and hypopharyngeal levels, with obese patients having smaller airways than controls. Although in some of these studies patients and controls were not matched for obesity, the finding of small retropalatal airway in OSA patients compared to weight-matched controls has been shown in additional studies (76,77). Using magnetic resonance imaging to compare obese OSA patients with weight-matched controls, fat deposition was increased at sites removed from the periluminal space, primarily in areas posterior and lateral to the oropharynx at the level of the palate, as well as within the soft palate (78,79). Differences in pharyngeal shape have also been observed between obese OSA patients and normal-weight controls (75,80). Specifically, when the pharynx was viewed in coronal section, awake OSA patients had an elliptically shaped airway channel, the long axes of which were oriented in the anteroposterior plane, while in normals the airway channel was oriented transversely. Obesity by neck fat deposition is associated with a shift in the hyoid bone caudally, possibly altering the pharyngeal patency and/or leading to greater UA collapsibility (81). Patients with OSA have been shown to have necks that are larger in circumference than those of weight-matched controls (82). Some of these features are present in nonobese individuals, and the causality of such associations can be challenged on the basis of the biochemical changes that may result from sleep hypoxemia and fragmentation (10).

Obesity-related decreases in lung volume, as discussed earlier in this chapter, may also result in greater instability of the UA, as lung volume has been directly correlated with UA size (83,84). Moreover, pharyngeal distensibility, or “compliance,” has been shown to be greater in both males and females with OSA than in obesity-matched controls using the acoustic reflection technique (85,86). Similar findings were obtained when lung volume was passively altered using continuous

positive airway pressure (85). Both increases in lung volume and pharyngeal volume and decreases in this measure of UA distensibility in obese sleep apneics after weight loss have been observed (87,88). Obese patients with a large neck and low FRC tend to have more collapsible velopharynx during wakefulness (89). In one study, a 17% reduction in BMI in moderately obese subjects resulted in both a decline in AHI and a 23% improvement in UA closing pressures during non-REM sleep, which indicates a specific beneficial effect of weight loss on improvement in pharyngeal function and sleep apnea (90). However, another study of weight loss found no correlation between values for UA closing pressure and obesity in patients with OSA. One possible explanation is that weight loss acts indirectly through changes in lung size rather than directly through an effect on UA mechanics. Another is a variability among people in regard to fat distribution and accumulation or susceptibility to OSA. Nevertheless, weight loss in obese individuals is one appropriate and specific therapy for OSA. However, the mechanisms explaining how obesity impairs upper airway structure may be more complex than a simple anatomic enlargement or impairment of structural stability.

## V OBESITY HYPOVENTILATION SYNDROME

Most obese patients with OSA are normocapnic when awake; estimates are that 10–15% of morbidly obese patients (BMI > 35) may develop a disorder of the respiratory control system manifested by CO<sub>2</sub> retention during wakefulness (91). This is referred to as the obesity-hypoventilation syndrome (OHS). The term Pickwickian syndrome has also been used to describe this syndrome (92). It has been defined using ABG values of PCO<sub>2</sub> > 45 often with a PO<sub>2</sub> < 55 (93). Despite a substantial body of literature on the clinical and physiologic factors in obesity, no one mechanism explains the pathogenesis of OHS.

One factor often emphasized is the influence of an impaired ventilatory drive to both hypoxia (94) and hypercapnia (22,95). Although the data are not consistent across all studies, simple obesity may be associated with reduced awake ventilatory chemoresponsiveness, although this is based on data from a limited number of subjects (53,96). Obesity accompanied by OSA may or may not be associated with a reduction in chemoresponsiveness. In an early study, ventilatory and mouth occlusion pressure responses to CO<sub>2</sub> rebreathing were reduced from normals in both eucapnic and hyper-

capnic OSA patients (97,98), and a relative decrease in the awake ventilatory response to  $\text{CO}_2$  in eucapnic obese OSA patients has also been documented more recently (99).

While it is assumed that obesity or body fat explains OHS, there are alternative explanations. These include genetic variations in ventilatory responses, interactions between the metabolic effects of obesity and respiratory control, and/or effects of comorbid cardiovascular or metabolic events also linked to obesity acting on respiratory control (10). Genetically obese (ob/ob) mice exhibit blunted hypercapnic response, independent of the presence of obesity; furthermore, administration of leptin seems to reverse this hypoventilation, irrespective of food intake and weight (100). These studies do make a strong case for the role of central mechanisms in the pathogenesis of obesity-hypoventilation syndrome. Two clinical studies demonstrated that dietary restriction in morbid obesity produces a depression in ventilatory responses and one could speculate that this could relate to lowered leptin levels (101,102). Another factor would be the mechanical impairment to inspiration due to either decreased respiratory system compliance (16,103) or to inspiratory muscle weakness (48). Respiratory drive requires not only activities in the brainstem but also the distribution of neuromuscular drive to the chest wall muscles such as the diaphragm and the intercostal muscles. Muscles can be compromised by fatty infiltration, and their mechanical action on ventilation influenced by abnormalities in chest wall compliance, i.e., the coupling between muscle activity and the generation of pressure for inspiration (13,27,104).

The increase in diaphragmatic electromyogram activity per unit increase in  $\text{CO}_2$  in subjects who are morbidly obese is three to four times that found in normal subjects (105). This high value is a reflection of the need to sustain a high level of diaphragm energy expenditure to maintain adequate ventilation, a demand that must increase further with a change to the supine position (48). The reduction in this relationship is indicative of a diminished capacity to increase respiratory muscle activity to meet demands for ventilation. The morbidly obese patient will exhibit static inspiratory pressures 60–70% of normal in both upright and supine positions (14,16,48,104). Therefore, increasing EMG activity acts to move the massive chest wall rather than increase ventilation (95).

The direct effects of obesity on muscle size and function are not resolved. In a Zucker rat model of obesity in which respiratory function changes are similar to those found in human obesity, there are greater size and number of muscle fibers in the diaphragm of obese than

of nonobese siblings (106). In contrast, in the obese (ob/ob) mouse model the diaphragm is thinner in obese than lean siblings (E. Schlenker, personal communication). Systematic analysis of respiratory muscle thickness and fiber types in obese individuals are not currently available. The degree of  $\text{CO}_2$  retention correlates with decrease in inspiratory strength, decrease in vital capacity, and a decreased ability to sustain a maximal voluntary ventilation (95,105). The latter finding, i.e., an inability to sustain a level of ventilation, may indicate a degree of respiratory muscle fatigue, which contributes to the development of a chronic hypoventilation syndrome (52,107). Disordered breathing during sleep, i.e., OSA, may result in hypoventilation in the awake state (64). Both blunted chemoresponsiveness and load compensation might result from the sleep fragmentation and episodic hypoxemia that occur in OSA. Increases in the ventilatory response to added resistive loads (97) as well as a more brisk  $\text{CO}_2$  response curve occur after treatment of OSA with nasal CPAP (108,109). These findings are interpreted to indicate that OSA may play a primary role in the blunting of respiratory responses.

Another factor contributing to hypoventilation is a pattern of breathing (high frequency and lower tidal volume) that leads to an increase in dead space ventilation. The respiratory control system determines ventilation by independent alterations in tidal volume and frequency (47), which must optimize ventilation in the face of challenges like exercise and sleep. Ventilation-perfusion ( $\dot{V}/Q$ ) mismatch results from shallow irregular breathing combined with or without compression by a thick chest wall (110), and is especially pronounced in the lower lung zones (43).

The severity of disease is directly related to the following factors: degree of hypercarbia, degree of coexisting hypoxemia, and presence of complications such as pulmonary hypertension  $\pm$  cor pulmonale, left ventricular failure, and polycythemia. Table 2 is a useful classification of severity of a hypoventilation syndrome. Patients who are in the mild category may only need periodic follow-up and enrollment in a weight loss program, while those who fall into the moderate to

**Table 2** Classification of Obesity-Hypoventilation Syndrome

|                | Mild   | Moderate | Severe  |
|----------------|--------|----------|---------|
| $\text{PCO}_2$ | 45–50  | 50–60    | > 60    |
| $\text{PO}_2$  | > 70   | 60–70    | < 60    |
| Complications  | Absent | Absent   | Present |

severe category need a detailed workup, as outlined in Table 2.

## VI MANAGEMENT STRATEGIES FOR OSA AND OHS

### A Clinical Studies of Weight Loss

Further evidence for a role of obesity in OSA comes from clinical studies of weight loss in patients with OSA. Some 17 studies have been reported to date, which have included a variety of weight loss methods, patient selection criteria, efficacy and outcome measures, and research designs. Surgical and nonsurgical approaches to weight reduction have been employed in patients with varying degrees of obesity and sleep apnea, and treatment follow-up has ranged from 2 to 24 months. Significant weight loss has been reported in most studies, with varying results. Improvement in sleep-disordered breathing, oxygen hemoglobin saturation sleep fragmentation, and daytime performance; related changes in UA function and to a much more limited extent airway structure have also been evaluated.

Despite this strong support for the role of obesity causal factor in OSA and the potential value of weight loss as a primary treatment intervention for obese patient with OSA, several key issues and concerns remain to be addressed. In particular, it is unclear from these studies whether a critical threshold level for weight loss exists and which patients are most likely to benefit from treatment. Also lacking is information about the relative risks and benefits associated with dietary or surgical weight reduction procedures in patients with OSA and selection of optimal treatment approaches for specific subgroup of patients. The mechanisms of treatment efficacy are also uncertain at this point. Finally, strategies for long-term maintenance of weight loss and associated improvement in OSA need to be developed and tested.

#### 1 Dietary Weight Loss and OSA

Eight small ( $n < 30$ ) uncontrolled studies of dietary weight loss ranging from 25% to 50% of baseline weight yielded mean 30–75% reductions in indices of sleep-disordered breathing (87,111–117). Two controlled dietary weight loss studies found mean weight losses of 9–17% yielded mean AHI decreases of 47% and 61%, respectively (90,118). Two small ( $n < 55$ ) longitudinal studies of SDB change in patients with sleep apnea found no statistically significant correlations between change in AHI and change in BMI (81,119).

Major issues remaining to be addressed in more detail and/or in less selective populations are: (1) the amount of weight needed to achieve significant improvements in both OSA and daytime somnolence; (2) associated structural or functional changes in the upper airway; and (3) maintenance of weight loss beyond the traditional 6 to 12-month observation period. Evidence from other sources suggests that relapse after 1 year is to be expected following weight loss by most methods (120,121).

A brief review of some studies can provide some insight into the level of current understanding. If weight loss treatment consists solely of instructions to reduce caloric intake and no special diets, medications, or behavior modification techniques are provided, there can occur an approximate 10-kg weight loss in the treatment group, associated with a significant decline in mean AHI from 55 to 30 events/hr (90) and improvements can be observed in mean and maximum nocturnal  $\text{SaO}_2$  and improvements in sleep quality and daytime alertness. In contrast to the “treatment” group ( $n = 15$ ), no changes were observed in weight, AHI, or nocturnal arterial oxygen saturation in the “control” group ( $n = 8$ ). A significant association was observed between the amount of weight loss achieved and improvement in mean fall in  $\text{SaO}_2$  during sleep ( $r = 0.69, p < 0.01$ ). In this study, while there was a trend in the direction of a lower AHI with weight loss, in other studies where weight loss is more significant there may occur an improvement in upper airway function and a reduction in OSA in non-REM as well as in REM sleep (118).

The effects of very-low-calorie diets (VLCD) on weight loss and sleep-disordered breathing have been investigated (112,114–116), with similar variability in both the amount of weight loss achieved and the improvement in OSA. In one study (112) it was noted that the effects of weight loss might be attenuated as there was detected a substantial degree of otorhinolaryngeal pathology (e.g., tonsillar hypertrophy, tongue enlargement) (115). Accounting for common upper airway problems, independent of the effect of fat accumulation, would be important in subsequent studies of weight loss using either dietary or surgical interventions. Unfortunately, none of these studies has systematically compared VLCD with more conventional forms of dietary weight loss in patients with OSA.

Finally, a combination of dietary intervention and cognitive behavioral therapy on weight loss, sleep apnea, and hypertension has been reported (113). Following an intensive, 20-week program of dietary intervention, exercise training, and cognitive-behavioral

therapy, a mean weight loss of 27 kg was achieved. This was associated with a significant change in AHI (mean decrease = 17 events/hr in seven patients) and improvements in blood pressure, vital capacity, and functional residual capacity. Additionally, a significant decrease in soft palate width has been observed following weight loss. Major weaknesses of the study were the small number of patients, the absence of EEG monitoring of sleep and assessments of daytime alertness, the concomitant use of antihypertensive and other medications, and lack of follow-up evaluation.

## 2 Anorexiant Drugs

Drug therapy, like other nonsurgical modalities, is accompanied by only a modest (10%) weight reduction and requires continued use to maintain this result. There is a paucity of experience with anorexiant in obese OSA patients. Though it showed initial promise in the long-term treatment of obesity (122), fenfluramine and phenteramine fell out of favor because of the risk for valvular heart disease (123,124) and have subsequently been withdrawn from the market. Newer agents include orlistat, an inhibitor of pancreatic and intestinal lipase, which prevents fat absorption from the gut, and sibutramine, a selective serotonin and norepinephrine reuptake inhibitor, which decreases food intake and increases thermogenesis. Although these agents could help in the medical management of obese patients with sleep-disordered breathing, neither agent has yet been studied in this population in a controlled setting.

## 3 Surgically Induced Weight Loss and OSA

Surgery directed at reducing obesity appears to have a substantial and consistent trend toward improvements in respiratory symptoms and in some cases respiratory function with weight loss. The Swedish Obese Subjects study randomized >2000 patients to either surgery or conventional treatment arms. The surgically treated group displayed a mean weight loss of 23% compared with the control group in whom the weight remained stable, and this was associated with improvements in dyspnea and reductions in witnessed apnea. In a study on 21 morbidly obese patients undergoing vertical-banded gastroplasty, BMI decreased from a mean of 41.5 preop to 31.7 six months after surgery, and was associated with a significant increase in FVC, TLC, FRC, and a significant improvement in inspiratory muscle endurance assessed by PmPeak/Pimax (125); there was a strong correlation between the degree of

weight loss and improvement in respiratory muscle endurance.

Dixon et al. (126) evaluated >300 patients with questionnaires pre- and postsurgery, and found that mean reductions of 48% of baseline weight resulted in a reduction in daytime sleepiness from 39% to 2%, and habitual snoring from 82% to 14%. None of the studies had polysomnographic confirmations of sleep architecture. Several studies have observed marked changes in nocturnal Sao<sub>2</sub>, and sleep continuing and architecture allowing surgical weight loss interventions. In the first case series (60) jejunoileal bypass surgery in four morbidly obese individuals (mean of 231.0 kg) produced a reduction in mean weight to 123 kg associated with a dramatic decrease in sleep-disordered breathing at 2 years from 78 to 1.4 events per hour. However, one subject died following surgery and was not included in the data analysis, and no long-term follow-up data are provided.

In morbidly obese patients receiving gastric bypass surgery two studies reported similar changes in both the amount of weight loss achieved and associated improvements in OSA and sleep architecture (127,128). Studies were lacking in a detailed description of postsurgical complications or longer-term assessment of treatment outcome.

Sugerman and coworkers (129) emphasized the role of gastric bypass surgery in the management of obesity-hypoventilation, as defined by PaCO<sub>2</sub> > 45 mm Hg. Those with significant OSA and apnea-induced arrhythmias also received tracheotomies at the time of gastric surgery. Based on preoperative polysomnography, 10 patients had obesity-hypoventilation syndrome, nine had OSA, and 19 had both. Of these, two died shortly after surgery, and an additional four patients were lost to follow-up. Follow-up studies performed at 3–5 months postsurgery revealed significant weight loss (a 62% reduction in excess body weight) associated with improvements in both OSA and daytime somnolence, as reported subjectively. Percent apnea time (total duration of apneas/total sleep time × 100) declined from a baseline of 44% to 8% following surgery. Unfortunately, no data were provided regarding arterial blood gases, sleep architecture, AHI, or nocturnal SaO<sub>2</sub> before or after surgery. As in the previous studies, these authors also failed to provide long-term assessment of surgical weight loss changes in OSA.

Vertical-banded gastroplasty was reported in morbidly obese patients (BMI >40) with a wide range of symptoms and degrees of OSA (111). Among patients with OSA there was a 30–38% reduction in BMI post-

surgery, and a decline in respiratory events during sleep from 85% to 100%. Eight OSA patients were followed and results collected while on dietary management alone, and reductions in BMI were less dramatic; one patient with the greatest amount of weight loss (33% decrease in BMI) was cured of his OSA, and two additional patients showed improvement (i.e., > 50% reduction) in sleep-disordered breathing. Duration of follow-up for either group was not specified.

Overall, impressive results have been observed in terms of weight loss, respiratory function, improvements in sleep quality, and reductions in sleep-disordered breathing. The studies are limited in scope and design and, as a series of case reports, represent a low level of evidence (Sackett level V) for efficacy of a therapeutic intervention (130). Methodological differences have been noted in each of the studies reviewed, including lack of controls for the effects of surgery or other forms of medical intervention, nor have the mechanisms of action been investigated. Insufficient data are provided regarding the risks and benefits associated with surgical weight loss for OSA, although a significant rate of postsurgical complications is to be expected (131). Finally, none of the studies to date has included assessment of waking performance following treatment including such features as arterial blood gases or changes in vigilance as a result of weight loss, nor has adequate long-term assessment of treatment effects been conducted in terms of either weight loss or improvements in sleep and sleep-disordered breathing (132).

## **B Adjunct Treatments to Weight Loss**

### **1 Noninvasive Ventilation**

Initially described by Sullivan et al. in 1981, application of positive airway pressure via a mask (nasal or full face) will restore upper airway patency and probably helps maintain lower airway patency during sleep in obese patients with OSA (133). It has been suggested that in patients with OSA who have OHS nasal CPAP on its own may be insufficient to suppress apneas and correct hypoxemias, particularly during REM sleep. The use of supplemental oxygen or preferably bilevel ventilation has been advocated. For some patients bilevel ventilation may be more comfortable than CPAP because the patient exhales against a lower mask pressure. Also, use of bilevel ventilation has been shown to result in unloading of the diaphragm in grossly obese subjects (134). Successful treatment depends on patient compliance. Studies have shown a reported compliance rate of 65–90% (135–137).

## **2 Medications**

### *a. Improve Respiratory Drive*

Acetazolamide at a dose of 250–500 mg/d will enhance respiratory drive by producing a metabolic acidosis through inhibition of renal tubular H secretion, by producing cerebral vasodilatation, and by direct stimulation of carotid afferents (138,139). Worsening of obstructive apneas was found in another study (140). The most notable side effects are paresthesias and hypokalemia. It may have a role in the treatment of subgroup of patients with periodic breathing or central sleep apnea (141).

Medroxyprogesterone (MPA) acts as a respiratory stimulant. Strohl et al. showed it to be effective in the reduction of apneas in four of nine patients (142). Those who responded had  $\text{PaCO}_2 > 46$  during wakefulness as compared to those who did not respond. MPA does not appear to work in patients with OSA who do not have hypercapnea (143). Side effects include impotence and feminizing effects. Its role is primarily in females with OHS, and it is given at 60–120 mg/d in divided doses.

Theophylline has been shown to be useful for central apnea and periodic breathing, particularly in patients with heart failure. It does not appear to be helpful for OSA, although the number of patients with OSA examined is limited (141,144,145). Its primary drawback is sleep disruption.

### *b. Management of Daytime Sleepiness*

Some studies have examined the role of modafinil in treatment of excess daytime sleepiness in obese patients with OSA. The data, while limited, suggest that modafinil may improve some aspects of alertness in patients with SAHS who remain sleepy during CPAP therapy (146,147).

## **3 Tracheotomy**

Indications include failure of/inability to tolerate medical measures and severe cor pulmonale or serious nocturnal arrhythmias (129). The morbidities, including risks of tracheal stenosis, infection and psychosocial problems, preclude its widespread use. Because these patients have large necks, special tracheotomy techniques are reported, including several skin-flap methods (148) that allow improved and easier stoma care.

## **4 Treatment of Coexisting Pathology**

As re-viewed elsewhere (*Chaps.* ), the probability of finding coexisting cardiovascular disease in obese individuals is quite high. Identification and management of

congestive heart failure and other causes for edema are likely to improve respiratory function including UA patency. Patients with obesity-hypoventilation tend to retain large volumes of fluid, which further worsens their respiratory mechanics, leading to a vicious cycle. Patients in fluid overload and cor pulmonale should be aggressively diuresed. Care should be taken to avoid excessive metabolic alkalosis by the judicious use of acetazolamide. Identification of upper airway processes like tonsillar enlargement or nasal obstruction are also important (115).

### 5 Supplemental Oxygen

In severe cases, marked daytime hypoxemia may persist despite of the above measures. These patients need conventional long-term O<sub>2</sub> therapy (> 18 hr/d) in addition to nasal CPAP or BiPAP to halt the progression of PH.

## VII OBESITY AND ASTHMA

An association between increase in BMI and asthma has been found in several studies (149). This association seems to be stronger in women. The increasing prevalence of obesity in developed nations may help explain concomitant increases in asthma prevalence. Although individuals with asthma may gain weight as a result of activity limitations, the relationship between BMI and risk of developing asthma is not known.

### A Epidemiological Studies

There have been many studies with varied design done in recent years in different age groups, in different parts of the world. These are summarized below.

#### 1 Studies in Adults

In a prospective study looking at factors influencing the rate of decline of ventilatory capacity in a cohort of 181 automobile workers, decrements in the FEV<sub>1</sub> in subjects <35 years old were influenced as much by excessive weight gain as by cigarette smoking. Loss of weight in those significantly overweight was frequently associated with improved lung function (150). In another prospective cohort study of female U.S. registered nurses [85,911 participants, aged 26–46 years) between 1991 and 1995, 1596 incident cases of asthma were identified on the basis of self-report of physician-diagnosed asthma. The relative risks of asthma for six increasing categories of BMI in 1991 were 0.9, 1.0, 1.1, 1.6, 1.7, and

2.7 (*P* for trend <.0001). Women who gained weight after age 18 were at significantly increased risk of developing asthma during the 4-year follow-up period (151). Chen found a 5% prevalence of self-reported asthma in 17,605 subjects aged 12 years or more who participated in the National Population Health Survey in 1994–95. He found that the prevalence of asthma increased with increasing body mass index in females, but not in males (35). Another study looked into the relationship between asthma medication and body weight in an adult Swedish population (*n* = 17,912). While no significant risk for developing obesity on asthma medication was seen, compared to patients with pharmacologically untreated asthma, they found significantly higher adjusted odds for asthma, in women (OR = 2.74) but not in men (OR = 1.57) with BMI ≥ 30 (152).

In a baseline survey of the Australian Longitudinal Study on Women's Health (*n* = 14,779), women in the highest BMI category (> or = 30) were found more likely to report asthma (153). Data from the British Cohort Study (BCS70) showed that the prevalence of asthma increased with increasing adult BMI, with a stronger association in women; odds ratios for overweight and obese women were 1.51 and 1.84, respectively. Similar associations with birth weight and adult BMI were present for wheeze but not for hay fever or eczema (154). Another British study, looking at pooled data from 1971 white males, found that severe obesity was a significant risk factor for recent asthma (OR 2.04), wheeze in the previous 12 months (OR 2.6), and asthma medication use in the previous 12 months (OR 2.83), but not for AHR (OR 0.87). FEV<sub>1</sub> and FVC were significantly reduced in the group with severe obesity, but FEV<sub>1</sub>/FVC ratio, peak expiratory flow (PEF) and mid forced expiratory flow were not different from the group with normal BMI. This study suggested that although subjects with severe obesity reported more wheeze and shortness of breath, which may suggest a diagnosis of asthma, their levels of atopy, airway hyperresponsiveness, and airway obstruction did not support the suggestion of a higher prevalence of asthma in this group (155).

#### 2 Studies in the Pediatric Age Group

Multiple population-based studies across different continents have found a strong association between self-reported asthma and obesity in the pediatric population (156–159). This association seems to be stronger among girls (156–158). In a study looking at ED visits in children aged 4–9 years seen with asthma, Belamarich

found that in the 9 months after baseline assessment, the obese group had a higher mean number of days of wheeze per 2-week period, and a greater proportion of obese individuals had unscheduled ED visits (160). In a prospective, longitudinal, open-label clinical trial, four groups of children from 8 to 16 years old were studied. Group 1 had 15 asthmatic nonobese children. Group 2 had 15 asthmatic obese children. Group 3 had 15 nonasthmatic obese children. The nonasthmatic obese children had a significant decrease in FEV1; meanwhile, the asthmatic obese children had a deeper decrease in FEV1 than the asthmatic nonobese children. Thus, obesity was seen to be a conditioning factor for bronchial hyperreactivity to the exercise (161). In a review of medical records from a urban community health center there were significantly more children with asthma (30.6%) who were very obese ( $\geq 95$ th BMI percentile) compared with controls (11.6%); the difference was significant for both sexes (162). Gokbel et al. found that pulmonary function changes after the exercise had a significant negative correlation with BMI and subscapular and biceps skinfolds (163). A similar study in children 6–10 years old demonstrated that significantly greater frequency and degree of bronchospasm of the smaller airways occur in obese children was partially related to the amount of subcutaneous fat (164).

## B Mechanisms

Possible mechanisms include progressive reductions in airway caliber as a result of chest wall restriction, increased airway resistance, and impairments in small airways function. Obesity predisposes to gastroesophageal reflux disease, an important risk factor for adult-onset asthma. It has also been postulated that the lower tidal volume of obese patients may result in less tidal stretching of airways smooth muscle and could promote airway narrowing and possibly airway hyperreactivity (165).

## C Effects of Weight Loss on Asthma

Five studies have all shown a consistent and significant benefit in asthma control in obese asthmatics. Thirty-two patients presenting for LAGB were found to have asthma preoperatively. On follow-up their mean BMI decreased to  $32.9 \text{ kg/m}^2$  from  $45.7 \text{ kg/m}^2$  prior to operation. All 32 patients recorded a lower asthma score postoperatively. There were significant improvements in all aspects of asthma assessed. These included severity, daily impact, medications needed, hospitalization, sleep, and exercise. The mean preoperative scaled asthma score fell from a mean of 44.5 to 14.3 (126).

Hakala measured the effects of weight reduction on peak expiratory flow (PEF) variability and airways obstruction, compared to simultaneous changes in lung volumes and ventilatory mechanics in 14 obese patients with stable asthma (166). The patients were studied before and after a very low calorie diet period of 8 weeks. As patients decreased their BMI from a mean of 37.2 to 32.1, diurnal PEF variation declined from 5.5% to 4.5%, and day-to-day variation declined from 5.3% to 3.1%. The mean morning PEF, FEV1, and FVC increased after weight loss. Functional residual capacity and expiratory reserve volume were significantly higher after weight loss. A significant reduction in R(AW) was found. In another study, 157 severely obese patients underwent silastic ring gastric bypass and were followed for a median 2.5 years. Median preoperative BMI was 45, and decreased significantly to 28 at 2 years post-SRGBP. Before surgery 34 patients were being treated for asthma. Withdrawal of all asthma medication was achieved after surgery in 17 of these patients (167). Similar results were seen in a series of 62 patients undergoing bariatric surgery. Postoperative use of medications for asthma was reduced by 100% (168). In a case-controlled study of 38 obese patients with asthma (BMI  $\text{kg/m}^2$  30–42), a supervised weight reduction program including 8-week very low energy diet resulted in a mean loss of 14.5% of their pretreatment weight, and 11.3% after 1 year. Controls had a weight loss of 0.2% at 8 weeks and a gain of 2.2% after 1 year. After the 8-week dieting period the difference in changes in FEV1 percentage from baseline in the treatment and control groups was 7.2%, in FVC was 8.6%, with a 13-mm difference in dyspnea on a visual analog score. These differences were still significant after 1 year. The reduction of rescue medication was 1.2 and 0.1 doses, respectively. The median number of exacerbations in the treatment group was 1 (0–4) and in the controls 4 (0–7) (169).

These data, while supportive, are by no means definitive of a causative basis for obesity in asthma. Management of asthma in obese patients is made difficult by the fact that use of systemic steroids is associated with significant weight gain. Also, smoking cessation frequently causes increased weight gain, which negatively impacts on smoking cessation efforts.

## VIII SUMMARY AND CONCLUSIONS

Obesity impairs respiratory structure and function, leading to physiological and pathophysiological impairments. The degree to which increased fat deposition

**Table 3** Areas of Needed Research

---

|  |
|--|
| Epidemiology/Physiology: Sharply defined epidemiological work to capture the intermediate phenotypes for obesity that confer risk for ventilatory impairment and sleep-disordered breathing. Examine interactions between risk factors for sleep apnea (craniofacial anatomy, hormonal status, ventilatory responsiveness, and family history) and obesity. Identify population and clinical subgroups at greatest risk for adverse clinical outcomes from obesity, including those defined by race, gender, or age. The genetic epidemiology of obesity and respiratory lung function, ventilatory control, and gas exchange. |
| Pathophysiology: Determine if sleep and sleep interruption impact on performance, eating behavior, and growth, particularly in obese school-age children. Describe the various outcomes and independence of interactions between obesity and sleep apnea on daytime performance and cardiovascular risk. Determine the basis for interactions among obesity and age in regard to upper-airway function in sleep apnea.   |
| Treatment: Determine the impact of interventions for obesity on ventilatory function and breathing during sleep, particularly during a preclinical phase (stage I). Compare effectiveness of behavioral interventions for nonapneic and apneic individuals. Estimate the extent of medical care utilization, health care costs, and measures of quality of life.   |

---

affects respiratory function may vary according to age, length of the obese condition, comorbidity, and other individual traits, including those related to chemore-sponsiveness, load compensation, and sleep-induced alterations in respiratory drive. The influence of obesity on pharyngeal function and the appearance of OSA appears related not only to BMI, but to measures of central obesity and neck size. How neck size is determined and related to other well-studied obese phenotypes remains to be determined by longitudinal studies or by cross-sectional studies in established cohorts being examined for obesity or diabetes. Also needed are outcome-based studies of the impact on obesity on cardiorespiratory morbidity with surgery and with the development of OSA. The classification presented in this chapter is intended to encourage thought and debate in this area. Obesity appears an important variable to examine in regard to respiratory health given that most studies involving weight loss show significant improvement or frank reversal of abnormalities in ventilatory control, respiratory mechanics, and illness like OSA and obesity-hypoventilation syndrome, which suggests that modafinil may improve some aspects of alertness in patients with SAHS who remain sleepy during CPAP therapy. Effective therapy for achieving weight loss would address perhaps half of the current patients diagnosed with OSA syndrome and could play a role in the prevention of OSA. The therapeutic avenues opened by molecular mechanisms for obesity and the obese phenotype will be particularly relevant to understanding sleep-disordered breathing in obesity.

There are gaps in our knowledge; some areas for further research are listed in Table 3. Studies have involved rather small groups of subjects, and the relationship between obesity and respiratory function has been handled by categorical analyses, whereas it is our suspicion that examination of measures of obesity and

measures of respiratory function during wakefulness and sleep as continuous variables might disclose new interactions, potentially important not only for therapy but also for public health.

## Obesity, Arthritis, and Gout

**Anita Wluka and Flavia M. Cicuttini**

Monash University, Melbourne, Victoria, Australia

**Tim D. Spector**

Guy's and St. Thomas' Hospital NHS Trust, London, England

### I INTRODUCTION

Musculoskeletal conditions affect 16% of all Americans (1). In 1988 it was estimated that the direct and indirect costs of these to the country were equivalent to 2.5% GNP (2). This was three times as great as the estimated cost in 1980. Musculoskeletal conditions are an important cause of acute and chronic disability, being amongst the most common causes of work disability, because of their prevalence and severity (2). Indeed, in the workplace, the cost of musculoskeletal diseases were the highest and second-highest disease categories in workers with BMI between  $\sim 27.5$ –30 and  $> 30$ , respectively (3).

The most common musculoskeletal condition is osteoarthritis (OA), which affects 12.1% of Americans between the ages of 25 and 74 years (4). Its prevalence increases with age, so that the socioeconomic burden to society will grow with our aging population. Gout is the most common form of inflammatory arthritis in males over 40 years old.

### II OBESITY AND OSTEOARTHRITIS

Osteoarthritis is a disorder of synovial joints characterized by deterioration and abrasion of the joint cartilage

and formation of new bone at the joint surfaces. Obesity is likely to be the most important preventable risk factor for knee OA. Overall, results to date suggest that the link between obesity and OA is more consistent in women and is strongest in OA of the knees and less conclusive in other joints. This has important implications since OA is an enormous public health problem in developed countries as it is the commonest single cause of disability (5) and the major reason for hip and knee replacements (6). The combination of its effect on patients and the therapeutic procedures used produces a huge burden on society (7). Recently, efforts have been focused on potential risk factors for OA with a view to identifying possible preventive measures. The management of obesity is likely to be a key factor in the management of OA.

#### A Association of Obesity and Osteoarthritis of the Knee

Cross-sectional epidemiological studies have consistently shown a relationship between obesity and knee OA, which has generally been stronger in women than in men. The reported increased risks have ranged from two- to seven-fold for women in the top tertile of BMI compared to women in the bottom tertile (8–14) (Table 1). The earliest survey to mention this link

**Table 1** Evidence of Association Between Knee OA and Obesity from Some Recent Cross-Sectional and Longitudinal Population-Based Studies

| Study                    | Comparison groups of body weight  | Relative risk of knee OA (95% CI) |
|--------------------------|---|-----------------------------------|
| Cross-sectional          |   |                                   |
| Felson et al., 1988 (12) | Quintile 5 (MRW $\geq 129$ ) <sup>a</sup> vs. quintile 1 (MRW < 105)            | Men 1.51 (1.14, 1.98)             |
|                          | Quintile 5 (MRW $\geq 128$ ) vs. quintile 1 (MRW < 100)                         | Women 2.07 (1.67, 2.55)           |
| Davis et al., 1990 (14)  | BMI > 30 vs. BMI $\leq 30$  | 3.64 (2.21, 6.02)                 |
| Hart et al., 1993 (16)   | Tertile 3 (BMI > 26.4) vs. tertile 1 (BMI < 23.4)                               | Women 6.17 (3.26–11.71)           |
| Longitudinal             |   |                                   |
| Anderson, 1988 (13)      | Minimum adult weight <sup>b</sup>   |                                   |
|                          | BMI > 27.3 vs. BMI < 27.3   | Women 2.66 (1.6, 4.42)            |
|                          | BMI > 27.8 vs. BMI < 27.8   | Men 0.65 (0.10, 4.36)             |
| Felson, 1992 (59)        | Weight gain > 2 units BMI over the 10 years prior                               | Per 2 units gain in BMI           |
|                          |   | 1.35 (1.11, 1.64)                 |

was by Fletcher 1945 (8). In 1958 Kellgren and Lawrence found that knee OA was commoner in obese people and twice as common in females as in males (9). Data from the large National Health and Nutrition Exam Survey (NHANES I), 1971–75, found that the risk of OA increased with degree of obesity and that long-term obesity was significantly associated with knee OA (13,14). Obesity was strongly related to bilateral knee disease (15).

A population-based cross-sectional prevalence study of obesity and OA in middle-aged females confirmed obesity as a strong risk factor for OA knees in women (16). This study showed a nearly 18-fold increased risk for bilateral disease. This same effect was also seen in the subgroup of asymptomatic women. The proportion of OA which was estimated to be attributable to obesity in this group of middle-aged women was 63%.

## B Association of Obesity with OA in the Different Knee Compartments

Until recently, little consideration was given to the multicompartimental nature of the knee joint in epidemiological studies of OA. However, recent work has suggested that a significant proportion of symptomatic knee OA may be caused by patellofemoral disease (17–19), which is not visualized by conventional anteroposterior radiography. Consequently, little attention has been focused on whether the risk factors for OA differ

among the different knee compartments. A recent population based case control study examined whether risk factors for OA differ between the different knee compartments (20). This study did not show a significant effect of obesity on the patellofemoral joint but showed an effect at the tibiofemoral joint. This case control study, based on small numbers, was the first to consider the possibility that OA in different compartments may have different etiologies and that previously described risk factors such as obesity may have differential effects in the different compartments. In contrast, data from a population-based cross-sectional study of middle-aged women showed it to be an important risk factor for both medial tibiofemoral and patellofemoral joint disease (21). This is an area where further work will be needed to clarify the role of obesity as a risk factor in OA in the different compartments of the knee. This is likely to have important implications for preventive strategies in OA of the knee and for our understanding of the pathogenesis of OA.

## C Evidence from Longitudinal Studies of the Association of Obesity with Knee OA

Longitudinal studies have consistently shown an association of obesity with knee OA (Table 1). The Framingham Study examined the association between obesity and knee OA in a longitudinal study. At the time of that study, the group had been followed up for 35 years (22).

Radiographs that were obtained on examination 18 (subjects' mean age 73) were used, together with weights on the same subjects that had been obtained at the beginning of the Framingham Study when the mean age of participants was 37. No radiographs were available at the age of 37, but the assumption when analyzing the data was that the prevalence of OA at age 37 was low. This study was able to look at obesity prior to the development of OA. A strong association between being overweight in 1948–1951 and having knee OA ~36 years later was found. This association was stronger for women than men after controlling for possible confounders such as age, uric acid level, and physical activity. Furthermore, this association was present for both symptomatic and asymptomatic disease. In addition, there was a stronger association with more severe, rather than mild, radiological disease. Similarly, the Johns Hopkins Precursors Study (23) examined the relationship between obesity and subsequent OA in men. In a prospective cohort of 1132, using 84 cases of incident hip and/or knee OA, the investigators were able to demonstrate a dose response relationship for increased body mass index (BMI) at a young age with an increased risk of knee OA. The Chingford population study of incident OA in women (24) found over a 4-year period that the odds ratio of developing incident osteophytes, but not joint space narrowing, was significantly increased in those in the highest tertile for BMI. These results suggest that higher BMI earlier in life may be a more important risk factor for the subsequent development of knee OA than heavier weight later in life.

These data are supported by other studies in which, although data on actual weight preceding the onset of OA were not available, self-reported, recall weights were used. In the NHANES study, the effect of past obesity on the risk of developing OA was examined by using self-reported minimum adult weight as a proxy measure of long-term obesity (13). In this study, past obesity was found to be associated with OA. In the Chingford population study of 1003 middle-aged women, a similar association was observed between self-reported minimum weight at age 20 and OA in middle age (16). In that study it was argued that the recalled weight was probably quite accurate as it coincided with the approximate age at which many of the women got married, thus improving the likelihood of accurate recall of their weight at that time.

Further evidence suggesting that obesity precedes OA, rather than the converse, is that the association between OA and obesity is strong even for individuals with radiological evidence of knee OA who are asymptomatic (13,16,21). This is important as radiological disease has been shown to correlate with later disability

(25,26). Furthermore, a strong dose response effect has also been observed between obesity and OA. Those individuals that were obese (BMI > 30) were shown to have a markedly increased risk of knee OA relative to those who were only modestly overweight (BMI > 25 to < = 30) (13). This dose response relationship provides additional evidence of a possible etiological effect.

#### **D Evidence from Twin Studies of the Role of Obesity in OA**

A further method for examining the association between obesity and osteoarthritis is via twin studies, which have been used to estimate the magnitude of the weight difference associated with the development of OA (21). Twin studies provide a special research methodology that, as well as assessing the relative contributions of genetic and environmental factors to a disease, may also be used to examine environmental risk factors in twin pairs discordant for that disease trait. The twin model used in this study enabled close matching of the diseased and nondiseased twin for genetic similarity and many known or unknown environmental factors, thus providing a useful tool to quantify the magnitude of the difference in obesity between the twin with disease and their cotwin with no disease.

The twin study confirmed that obesity is a strong risk factor for OA of the knee, with twins with OA of the tibiofemoral and patellofemoral joints of the knee tending, on average, to be 3–5 kg heavier than their cotwin (Fig. 1). This weight difference was also observed in asymptomatic women, again suggesting that obesity is a cause of OA rather than the converse. After adjusting for other potential risk factors, the results showed that for every kg increase in weight, a twin had a 14% increased risk of developing tibiofemoral osteophytes and a 32% increased risk of developing patellofemoral osteophytes compared to their cotwin. These results were consistent with a previous population study, in a similar age group of women, that showed that the risk of knee OA increased by 35% for every 5 kg of weight gain (16). This suggests that in middle-aged women even small increases in body weight are associated with significant increases in risk of developing OA. Risks in men, however, cannot be extrapolated from these results, and separate studies are needed.

#### **E Association of Obesity and Osteoarthritis of the Hand**

Results regarding the association of obesity with hand OA are conflicting. OA of the distal interphalangeal joints has been associated with obesity in some studies,

**Figure 1** Body weight for twins with osteoarthritis in the tibiofemoral joint (TFJ) of the knee, the patellofemoral joint (PFJ) of the knee, and the carpometacarpal (CMC) joint of the hand. The weight differences between the twins with OA and the twins without OA were significant at all the above joints: TFJ ( $P < .001$ ), PFJ ( $P < .001$ ), CMC ( $P < .002$ ).

although principally in men (9,27). Secondary analysis of data from the National Health Examination Survey showed a significant association of BMI with the presence of hand OA in men after adjustment for age, race, and skinfold thickening but not after adjustment for waist girth and seat breadth (28). An association between radiographic hand OA and BMI in men was also observed in the longitudinal prospective study of 70-year-old people in Goteborg (29). An association between obesity and finger OA was observed in the New Haven Survey, with this association being stronger in females (10). The Fallon Community Health Plan Study of OA (30), a case control study, found that obesity and hand OA were associated.

An association was observed between BMI and the grade of hand OA for women in the Tecumseh Community Health Study (31). Obesity was also modestly associated with distal interphalangeal and carpometacarpal OA, but not with the proximal interphalangeal OA in the women in the Chingford Study (16).

Data from a twin study showed a mean weight difference (95% CI) within twin pairs discordant for carpometacarpal osteophytes of 3.06 (0.83, 5.28) kg (21). The results suggested that there was a 9% increase in risk of developing carpometacarpal osteophytes for every kg increase in body weight. However, there was no significant difference in weight within twin pairs discordant for osteophytes at the distal interphalangeal (distal interphalangeal) or proximal interphalangeal (proximal interphalangeal) joints.

However, other studies have found no relationship between obesity and hand OA. No association was observed between indices of obesity and hand OA in men in the Baltimore Longitudinal Study of Aging (32) or for women between BMI and hand OA in the National Health Examination Survey (28). The Ulm Os-

teoarthritis Study, (33) which examined 809 consecutive patients who underwent hip or knee replacement for OA, also found no association.

## F Evidence from Longitudinal Studies of the Association of Obesity with Hand OA

Less information is available on the effect of long-term obesity and hand OA. One of the few studies to examine this was the Tecumseh Community Health Study, a longitudinal study that investigated the role of obesity in the etiology of hand osteoarthritis (34). This study, conducted in Tecumseh, MI, began in 1962 with baseline examinations of clinical, biochemical, and radiologic characteristics. A 1985 reexamination of the cohort characterized osteoarthritis status in 1276 participants (588 males and 688 females) aged 50–74 years at this follow-up. Baseline obesity, as measured by an index of relative weight, was found to be significantly associated with the 23-year incidence of osteoarthritis of the hands among subjects disease free at baseline. Greater baseline relative weight was also associated with greater subsequent severity of osteoarthritis of the hands. However, the difference between baseline and follow-up weight values was not significantly associated with the incidence of osteoarthritis of the hands. Furthermore, there was no evidence that development of osteoarthritis subsequently led to increased incidence of obesity.

## G Association of Obesity and Osteoarthritis of the Hip

The available data suggest that there may be a modest association between hip OA and obesity (9,11,27). When data from 4225 persons from the national Health and Nutrition Examination Survey (HANES) were examined by dividing subjects into four groups on the basis of sex and race, relative weight was weakly associated with OA of the hips in white women and non-white men (11). A case control study that examined BMI at ages 20, 30, 40, and 50 years in 239 men who had just received a hip prosthesis because of osteoarthritis and in 302 controls randomly selected from the general population (35) showed that men with a BMI  $> 1$  SD above the mean had a greater relative risk of developing severe OA than with men with a BMI  $< 1$  SD below the mean. Those slightly obese at the age of 40 years had a relative risk of 2.5 for later surgery of the hip.

In contrast, data from the First National Health and Nutrition Examination Survey (NHANES-I) did not support this (36). Obesity, and fat distribution were not

associated with hip osteoarthritis. The Johns Hopkins Precursors Study (23) found no relationship between BMI in the preceding three decades with subsequent hip OA. Other studies have also found no association between obesity and hip OA (30,33).

**H Possible Mechanisms for Obesity in the Pathogenesis of OA**

OA is a disease of cartilage in which cartilage breakdown and erosion are accompanied by bony changes such as osteophytes, subchondral sclerosis, and bony cysts. Although the mechanisms by which obesity may lead to OA are unknown, three hypotheses have been proposed (14,15,37): (1) obesity increases the load across the knee joint resulting in increased or abnormal stress and resultant deterioration of the joint structures; (2) obesity acts indirectly by metabolic changes associated with increased fatness such as glucose intolerance, hyperlipidemia, hyperestrogenemia, or changes in bone density; and (3) elements of the diet that result in obesity, such as high fat content and adversely affect bone, cartilage, or other joint structures (Table 2).

Obesity may initiate cartilage breakdown or may promote joint destruction after the initial incipient lesion. Biomechanical characteristics may be accentuated by obesity. In a study of 300 subjects, most of the effect of BMI on the severity of OA in medial tibiofemoral osteoarthritis was explained by varus malalignment of the joint (38). Furthermore, this study showed that obese subjects with valgus malalignment had hardly any increase in OA prevalence. These results suggest that a major mechanical influence of obesity is modified by alignment. Whether obesity influences

alignment or the two are independent is unclear. Although obesity possibly leads to disease because it causes increased force on the cartilage, it also may produce disease by increasing subchondral bony stiffness (39) and by making subchondral bone less deformable to impact loads. This stiff bone would then transmit the increased force to underlying cartilage, making it more vulnerable.

A number of factors suggest a metabolic/systemic component to OA. These include the female preponderance, the menopausal onset of generalized OA, the unequal effect of obesity on knee and hip OA, and the inverse relationship with osteoporosis. Furthermore, obesity is also linked to OA of the fingers and the base of the thumb, in which mechanical force is less likely to play an important role.

**I Evidence for Obesity Acting Via a Systemic Mechanism**

**1 Association Between Osteoarthritis and Other Metabolic Conditions**

*a. Hypertension*

On analysis of the data from the 1960s survey in Leigh and Wensleydale, Lawrence found that hypertension was associated with generalize OA in men and with knee OA in hypertensive, nonobese females (40). The relationship was between diastolic blood pressure and knee OA in both obese and nonobese females, and this association remained in each 5-year age group from 45 to 69. The association between hypertension and OA was also observed in the Chingford population study which showed that “ever treated” hypertension was associated with the development of OA and that this association was strongest for those with bilateral knee disease (41).

However, other studies have failed to confirm an association between OA and blood pressure. No association was found in a study of 70-year-old people in Goteborg (29). In univariate analysis of NHANES 1 data, an increase in recorded diastolic and systolic blood pressure was found in females with knee OA, but this association disappeared after adjusting for weight (42). Similarly, in the Baltimore Longitudinal Study of Aging (43), men and women with knee OA had higher unadjusted blood pressure than those with normal radiographs. However, after adjustment for age and weight, the effect was lost in men. Although women with knee OA had higher systolic pressure than those with normal knees, the mean pressure was within the normal range.

**Table 2** Possible Mechanisms for Obesity in the Pathogenesis of OA

|  |

| ?Excess endogenous steroids  |
| Genetic association of two common diseases   |
| Dietary  |
| High fat content resulting in abnormal joint structures  |

### b. Cholesterol

A significant association was found with hand OA and above average measured serum cholesterol in women in the 1960s survey in Leigh and Wensleydale (44). However, the association disappeared in those with very high serum cholesterol. Furthermore, Lawrence (40) found that subjects with OA and hypertension in this same population did not have an association with high serum cholesterol or uric acid. In analyses of the data from NHANES 1, the study of 70-year-old people in Goteborg and the Baltimore Longitudinal Study of Aging, serum cholesterol was not significantly associated with either unilateral or bilateral knee OA (15,29,43). In contrast, the data from the Chingford population study suggested an association between bilateral knee disease and hypercholesterolemia (41).

### c. Glucose

Few studies have examined the association between blood glucose and OA. Cimmino et al. (45) studied 1026 subjects with OA from clinics and compared them to 220 healthy population controls and found slightly higher levels of plasma glucose in females in the OA group after adjusting for age. A study comparing 25 female diabetic patients with knee OA and 48 non-diabetic females who were matched on age, weight, symptoms, and duration of OA found an increased incidence of osteophytes on the radiographs of the diabetic patients, while the joint space narrowing and sclerosis were equal in the two groups (46). An association between serum glucose and osteoarthritis was also observed in the Chingford population study (41). In this study, raised blood glucose was a significant factor in all forms of knee OA, but the association was strongest for those with bilateral knee disease (41). It has been speculated that the link between diabetes and OA may be through elevated growth hormone levels that alter cartilage metabolism and increase bone density (14,15). Increased bone density associated with obesity has been hypothesised to increase the forces acting on the cartilage, thus predisposing the development of OA (14,15). However, these theories have not been well examined and not all epidemiological studies have shown an association between serum glucose and OA. In the analyses of the NHANES 1 data, self-reported diabetes was not associated with either unilateral or bilateral knee OA (15). Furthermore, no association was observed between blood glucose levels and OA in a study of 70-year-old people in Goteborg (29). Indeed, in the Baltimore Longitudinal Study of Aging, no associ-

ation was noted between fasting glucose and OA, but men with OA had lower 2-hour glucose in a glucose tolerance test than those without OA (43).

### d. Uric Acid

Data from the New Haven population survey showed that a raised serum uric acid level was significantly associated with OA, with the association being stronger in women than in men (6). In univariate analysis of NHANES I data, hyperuricemia was found to be related to knee OA in women, but the association disappeared after adjusting for body weight (13). There was no significant association with either unilateral or bilateral knee OA (15). This is further supported by a study of 70-year-old people in Goteborg (29), where no association was observed between serum uric acid level and OA. In contrast, the data from the Chingford population study suggested a possible association between raised serum uric acid levels and bilateral knee disease (41).

### e. Summary

The data suggesting a link between OA and raised serum glucose, cholesterol, uric acid, and hypertension remain inconclusive. However, one possible explanation for an association among hypertension, hyperlipidemia, and OA is insulin resistance or Reavens syndrome (47). This syndrome may be a distinct genetic trait, or it may represent a physiological adaptation to chronic obesity (48).

## 2 Association Between Osteoarthritis and Body Fat Distribution

Adipose tissue distribution is associated with a number of metabolic complications, with a pattern of central body fat (particularly abdominal fat) indicating increased risk of diabetes, cardiovascular disease, and mortality, independent of degree of obesity (49). Recent interest has focused on the distribution of body fat in OA in an effort to understand whether systemic factors are important in the development of OA. Analysis of the NHANES data showed that BMI correlated best with presence of OA using different anthropomorphic measurements suggesting that body fat may be more important than the absolute weight (37). In this study there was a significant association between hand and foot OA and seat breadth in men, odds ratio 1.45 (1.03–2.06). Although this association was also observed in women, the confidence intervals included one. However, no association was found in this study

between a centralized pattern of body fat distribution with hand or knee OA. In fact, this study found some evidence for of an association for a peripheral body fat pattern and combined hand and feet OA (14). Consistent with these observations, the Chingford population study of middle-aged women (41) and the Baltimore Longitudinal Study of Aging (50) of both women and men also failed to show an association between body fat distribution and OA, independent of body weight.

### 3 Summary

Together these data support a greater contribution of mechanical as opposed to systemic factors to explain the association between obesity and OA. The results would suggest that peripheral distribution of fat may act as a mechanical effect rather than a metabolic cause of OA. However, there is increasing evidence that OA is not a single disorder but a heterogeneous group of disorders. It is postulated that a complex interplay of several factors may result in a common pathway of joint damage. Therefore, it is possible that obesity has a mechanical effect on some joints and a metabolic effect on other joints. Several studies have shown an association of obesity with hand OA (9,10,27,29). Thus, it may be, for example, that obesity causes knee OA because of an increase in mechanical stress across the joint but that the effect of obesity on the small joints of the hand is through metabolic consequences.

### J Role of Obesity in Progression of OA

The natural history of knee osteoarthritis is poorly understood, and few studies have any detailed data on prognostic factors such as obesity, although the available data suggest that obesity is important. In a small group of clinical cases followed up for 11 years, there was no clear effect of obesity (51). However, in the EPOZ study, Schouten et al. (52) found that obesity, age, Heberden's nodes and valgus deformity were all associated with cartilage loss over a 12-year period. Factors related to joint space progression in the multicenter French study were obesity and number of affected joints (53). A recent study that examined the rates of incident OA in the contralateral knee in a general population sample showed that in middle-aged women with early unilateral osteoarthritis of the knee, a high percentage (34%) develop OA in the contralateral knee within 2 years, while 22.4% progress radiologically in the index joint. Obesity appeared to have a marked effect on the incidence rates, with nearly a fivefold increase in overweight women compared to thin women.

This is supported by a further study that showed that the odds ratio for BMI was 11.1 (3.3 to 37.3) for the fourth versus the first quartile (52). BMI was also found to be related to loss of cartilage in those that had OA (52).

### K Association of Obesity with Symptoms and Disability in OA

Most nonfatal chronic conditions are strongly age related (53), their prevalence rising with increasing age of the population. Thus, as the total population continues to age owing to the decrease in birth rate and to recent declines in mortality in the older age groups, the burden of nonfatal diseases and impairments will continue to increase. This has highlighted the need to examine prognostic factors for disability. Using the 1984 Supplement on Aging conducted by the National Center for Health Statistics, the risk factors for disability among U.S. adults aged 55+ who had arthritis were compared to those who did not have arthritis (54). This study showed that obesity was strongly implicated in disability once arthritis was present. Thus, not only obesity is a risk factor for developing OA, but it also contributes to the disability once it occurs. The contribution of obesity to symptom development in individuals who already have the pathological changes of OA is unclear. Studies that have assessed whether obese subjects with concurrent radiographic OA are more likely to have symptoms have yielded conflicting results (11,55).

### L Is Weight Loss Effective in Reducing the Symptoms of OA?

An early study examined this question in subjects at least 25% above their ideal weight (56). The study was a placebo-controlled trial of 3 months of therapy with phentermine to achieve weight loss in patients with hip or knee OA. At 6 months, weight loss of 12.6% (6.3 kg) in the phentermine group and 9.2% (4.5 kg) in the control group was achieved. Reduction in pain correlated with weight loss, more strongly for knee than hip pain. A second study examining the effect of weight loss in patients following gastropasty on musculoskeletal symptoms (57) found a marked reduction in symptoms. However, not all musculoskeletal complaints were related to OA. These data suggest that weight loss reduces the symptoms of OA.

Which component of weight loss contributes most to reduction in symptoms was studied recently (58). Forty new patients with radiographic and symptomatic OA and BMI > 26.4 were treated with Ranzile (NSAID) for at least 4 weeks. Twenty-two were randomized to

receive a controlled calorie weight loss diet and Mandoz (an appetite suppressant, Sanorex, Sandoz), and 18 to receive advice only. All were given ongoing NSAID therapy (Rantudil) and advised to walk for up to 30 min continuously per day during the 6-week trial. Three in the control group forgot to wear pedometers for several days and were excluded from the study. The treatment group lost more weight and was more active than the control group. Nineteen of 22 (86.4%) in the treatment group improved symptomatically, compared to 4 of 15 (26.7%) in the advice-only group. In the treatment group, symptomatic relief of knee OA was most strongly associated with reduction in body fat (2.4%, SD 2.6) and physical activity (7.5, SD  $1.7 \times 10^3$  steps per day). Physical activity and reduction in body fat percent were related.

#### **M Is Weight Loss Effective in Reducing the Risk of OA?**

Few studies have looked at the effect of weight loss in subjects who have established disease. Felson et al. (59), in the Framingham cohort, observed that weight loss in middle and later adult life substantially reduced the risk of symptomatic OA of the knee. To evaluate the effect of weight loss in preventing symptomatic knee osteoarthritis, women who participated in the Framingham Knee Osteoarthritis Study (1983–85) were examined. Sixty-four out of 796 women studied had recent-onset symptomatic knee osteoarthritis (knee symptoms plus radiographically confirmed osteoarthritis) and were compared with women without disease. Weight change significantly affected the risk for the development of knee osteoarthritis. For example, a decrease in body mass index of 2 units or more (weight loss, ~5 kg) over the 10 years before the current examination decreased the odds for developing osteoarthritis by over 50% (odds ratio, 0.46; 95% CI, 0.24–0.86). Among those women with a high risk for osteoarthritis due to elevated baseline body mass index ( $\geq 25$ ), weight loss also decreased the risk (for 2 units of body mass index, odds ratio, 0.41). Weight gain was associated with a slightly increased risk for osteoarthritis, which was not statistically significant, while weight loss reduced the risk for symptomatic knee osteoarthritis in women. Furthermore, extrapolating from cross-sectional data suggests that risk of knee OA increases by 35% for every 5 kg of weight gain (16).

The available data would suggest that reduction or maintenance of weight may have an important role in the prevention of OA. However, there is little data on whether weight loss affects the long-term progression of OA and this area needs further work.

### **III OBESITY AND GOUT**

There has been an increase in prevalence of gout since World War II (60). Although increased awareness of this disease may in part explain this, and milder cases are being identified, particular interest has focused on the role of changes in diet and weight over this time. The evidence from cross-sectional and prospective studies for an association between obesity and gout is presented in the following sections.

#### **A Evidence from Cross-Sectional Studies for Obesity as a Risk Factor for Gout**

A large body of evidence exists to support an association between gout and obesity. The New Haven survey showed that certain metabolic conditions, including hyperuricemia, were associated with obesity (10). In a cross-sectional study of 73,000 women aged 30–49, obesity was shown to be significantly associated with gout ( $P < .001$ ) (61). In 460 apparently healthy Dutch men and women aged 65–79 years, serum uric acid level was found to be positively associated with body weight, body mass index, body fatness, and lean body mass in men but not in women (62). In a study of 7735 middle-aged men in 24 British towns, a positive association was observed between BMI and gout (63).

The association between obesity and hyperuricemia has also been observed in other ethnic groups. A survey of 115 Maori men of working age showed a strong relationship between hyperuricemia and obesity (64). In Melanesian and Asian Indians in Fiji, BMI was shown to have a significant and independent association with plasma uric acid levels in both nondiabetic and diabetic men and women (65). However, the most extreme example of an association between gout and obesity was seen in sumo wrestlers, who do not appear to have any underlying genetic predisposition to gout (66). In a study of 96 sumo wrestlers in Japan, mean serum levels of uric acid were significantly higher than those obtained in 89 age-matched healthy males. Weight correlated significantly with uric acid.

Some recent data have suggested that body fat and the distribution pattern of fat may be more important than total weight as a risk factor for gout (67). The association between fat distribution and gout was examined in 95 overweight adult men and 210 overweight adult women (67). It was found that, adjusted for age and body mass index, a high waist-thigh circumference ratio was a risk factor for gout, particularly in women. The association of waist-hip circumference ratio with gout was less pronounced in men. Visceral fat (estimated from abdominal CT scans) was shown to be

independently related to serum uric acid concentration, uric acid clearance, and uric acid/creatinine ratio, while BMI and subcutaneous fat were not (68).

### **B Evidence from Longitudinal Studies for Obesity as a Risk Factor for Gout**

The association of obesity with gout is also supported by longitudinal studies. The Johns Hopkins Precursors study, a cohort study of medical students, was examined with the aim of identifying potentially modifiable risk factors for the development of gout (69). Predominantly young (median age, 22 years), white, male students ( $n = 1271$ ) received a standardized medical examination and questionnaire during medical school. The outcome measure was the development of gout. Sixty cases of gout (47 primary and 13 secondary) were identified among 1216 men; none occurred among 121 women. In this study, body mass index at age 35 years, excessive weight gain between cohort entry and age 35 years were significant risk factors for gout in univariate analysis. Multivariate analyses confirmed the association of BMI at age 35 years and excessive weight gain as risk factors for gout.

Data from the Harvard Growth Study of 1922–1935 was used to examine the long-term effect of obesity in adolescence on morbidity, including the development of gout (70). A total of 508 lean or overweight adolescents 13–18 years old that participated in the Harvard Growth Study were included in this subanalysis. Overweight adolescents were defined as those with a BMI that on two occasions was greater than the 75th centile in subjects of the same age and sex in a large national survey. Lean adolescents were defined as those with a body mass index between the 25th and 50th centiles. The risk of gout was increased among men who had been overweight in adolescence. Overweight in adolescence was a more powerful predictor of this risk than overweight in adulthood.

In hyperuricemic men, a further increase in BMI has been shown to be a predictor for the development of gout (71).

### **C Association of Gout and Other Metabolic Disorders**

Hyperuricemia has been shown to correlate with a cluster of metabolic and hemodynamic disorders closely associated with insulin resistance syndrome (IRS) in young, apparently healthy individuals (72). After adjustment for sex, serum uric acid concentration showed positive associations with BMI, waist/hip girth, waist/thigh girth, and subscapula/triceps skinfold ratios. Fur-

thermore, serum uric acid was also positively correlated with fasting insulin, serum triglycerides, and LDL cholesterol, and negatively with HDL/total cholesterol ratio. This has been confirmed in other studies (73). Furthermore, urinary uric acid clearance appears to decrease in proportion to increase in insulin resistance in normal volunteers, leading to an increase in serum uric acid concentration. Thus, it appears that modulation of serum uric concentration by insulin resistance is exerted at the level of the kidney (73). Other studies investigating the relationship between gout and hyperuricemia and coronary artery disease have suggested that hyperuricemia, as a component of IRS (but not independently), may act as a risk factor for coronary artery disease (74,75).

Thus, obesity has a number of effects on urate metabolism, which include decreasing urate clearance (73) and increasing urate production (76). It has been suggested that other factors such as muscle mass may also play a role in producing hyperuricemia (77). Weight reduction has been associated with a modest lowering of the serum urate concentration (78).

### **D Diet**

It is thought that the increase in the prevalence of gout the last century may relate to the changing nutritional patterns associated with increasing industrialization (79). Genetic factors and nutrition combine such that the disease may become manifest. Interest has largely focused on the more abundant diet that is also richer in purines. For example, a study in the Ukraine showed that in the period from 1925–28 to 1970–71 there was an increase in the consumption of animal products (milk, meat, fish, eggs), sugar, vegetables, and fruits, and a fall in the consumption of cereals (bakery products, grits, macaroni, beans) and potato (80). In parallel with these dietary changes, the incidence of diseases such as gout increased over the same time period (80).

Population-based studies have confirmed the association between diet and gout. A study of 460 apparently healthy Dutch elderly aged 65–79 years showed that serum uric acid correlated with alcohol intake (men) and consumption of meat and fish (women), and inversely with consumption of bread, margarine, and milk products (women), independently of confounders such as body mass index (62). A community-based survey of 1738 registered residents  $\geq 30$  years of age in Pu-Li Township, Taiwan, from 1987 to 1988, showed that organ meat consumption significantly correlated with hyperuricemia after simultaneously controlling for weight (81).

Migration studies have also suggested a role for a richer diet in gout. The incidence of hyperuricemia and gout has been well recognized to be higher among Filipinos in Hawaii, Alaska, and mainland United States than in their native country (82). It appears that Filipino hyperuricemia may become manifest because some Filipinos possess a renal defect that may lead to hyperuricemia due to renal inability to compensate for an increased purine intake which may occur in the shift from a low-purine Filipino diet to a high-purine Western diet in the new environment (82).

To examine the effect of ingesting some purine-rich foods (beef liver, haddock filets, and soybeans) on uric acid metabolism, a crossover study was performed where three isoenergetic and isonitrogenous meals were fed to 18 male subjects with no history of gout or kidney disorder during a 3-week period (83). Only the content of uricogenic bases (adenine and hypoxanthine) varied among the test meals. Ingestion of all experimental meals caused an increase in serum uric acid levels at 120 min, and this increase was more marked (about twofold) with haddock and soybean ingestion. In all groups, the postprandial serum uric acid levels at 240 min were lower than those obtained at 120 min, but still remained elevated in comparison to the fasting level. As expected, 24-hr urinary uric acid excretion was similar for the three test meals owing to the isonitrogenous load of proteins and purines. This study suggested that assessment of each purine base content rather than the total purine content of foods may be important in the management of hyperuricemic individuals.

Conversely, Dessein et al. (84) theorized that if hyperuricemia were a component of insulin resistance syndrome, then loss of weight through moderate limitation of caloric and carbohydrate intake, together with an increased proportion of protein and replacement of saturated by unsaturated fat should reduce gout and hyperuricemia—despite this being the converse to the diet recommended to reduce the purine load. In a pilot study of 13 men (one normal BMI, six overweight, six obese) with acute intermittent gout, weight reduction reduced the frequency of episodes of gout and level of hyperuricemia and improved the serum lipid profile. This warrants further investigation.

## E Alcohol

Many studies with different study designs and in different populations have now shown a relationship between alcohol consumption and gout (85–91). For example, in a population-based study in Denmark, 5249 males aged between 40 and 59 were interviewed to identify a history

of gout (91). A total of 104 men who had experienced gout were compared to 208 computer-selected age-matched controls drawn at random from the entire sample. Alcohol consumption was higher in gout cases than in controls. In a cohort of 2046 initially healthy men in the Normative Aging Study followed for 14.9 years with serial examinations and measurement of urate levels, alcohol intake was a strong predictor of gout when examined in a proportional hazards model (92). In a longitudinal cohort study of hyperuricemic men, persistent alcohol consumption was a predictor of incident gout (71).

Migration studies have also confirmed the association between alcohol and gout. In a study of the prevalence and 14-year incidence of clinical gout in the Polynesian population of Tokelauans living in the Pacific Basin, nonmigrant Tokelauans living in their isolated atoll homeland being compared with migrant Tokelauans living in urban New Zealand (93). Self-reported alcohol consumption at entry to the study was a strong predictor of gout in men. Factors predisposing to acute gout were investigated in a case control study (94) of 70 patients with acute gout and matched for age and sex controls. Gout was significantly associated with obesity (odds ratio 3.7; 95% CI 1.4, 9.1) and high alcohol intake (odds ratio 3.3; 95% CI 1.1, 9.8). In these patients, it was estimated that 23% of gout was attributable to obesity and 16% to high alcohol consumption.

To determine the contribution of alcohol to increased production and decreased excretion of uric acid, a study was performed where oral ethanol (1.8 g/kg body weight every 24 hr) for 8 days or intravenous ethanol (0.25–0.35 g/kg/hr) for 2 hr was given to six patients with gout (95). The results of this study suggested that ethanol increases urate synthesis by enhancing the turnover of adenine nucleotides (95). A further study showed that chronic oral ethanol administration was associated with increased serum urate, urine uric acid excretion, urine uric acid clearance, and oxypurine excretion (96). The daily rate of uric acid turnover was significantly increased. Intravenous ethanol administration was associated with increased uric acid excretion, increased uric acid clearance, and significantly increased oxypurine excretion. Excretion of radioactivity derived from intravenously administered adenine increased significantly. It concluded that hyperuricemia related to ethanol consumption at lower blood ethanol levels (<150 mg/dL) results from increased production of uric acid probably secondary to accelerated degradation of adenine nucleotides.

Although red wine and not beer drinking has traditionally been linked to gout, beer drinking may have an

additional effect on the risk of gout. A recent study of 61 men with gout and 52 control subjects showed that the patients with gout drank significantly more alcohol and that the average daily intake of most other nutrients, including total purine nitrogen, was similar (97). Beer was the most popular beverage, and 25 (41%) of those with gout consumed >60 g alcohol daily (equivalent to 2.5 L beer). The heavy drinkers had a significantly higher intake of purine nitrogen, half of which was derived from beer. Though the effect of ingested purine on the blood uric acid was difficult to estimate in this study, it was probably sufficient to have a clinical effect, augmenting the hyperuricemic effect of alcohol itself. A further study attempted to simulate the beer-drinking habits of gout patients and examine the effect on uric acid levels (98). Beer or squash was drunk over a 4-hr period on two successive days by five gouty and five normouricemic men. Serum lactate increased with beer and squash, but elevation of plasma uric acid was confined to beer drinking. Urate clearance increased with both beverages, but 24-hr uric acid excretion was accentuated only by beer. The purine content of several beers was measured and the principal constituent found to be guanosine, which is probably the most readily absorbed dietary purine. It was concluded that the hyperuricemic effect of beer was mediated by the digestion of purines contained by the beer and by an effect of ethanol on uric acid synthesis. However, there was no evidence that beer taken in usual quantities reduced the renal excretion of uric acid.

#### IV SUMMARY

Obesity is an important risk factor for osteoarthritis and gout, which are two common, chronic diseases associated with significant morbidity and cost to the community. Preventive efforts to reduce obesity in the population are likely to have a major impact on these two conditions.

## Obesity, Pregnancy, and Infertility

**Stephan Rössner**

Huddinge University Hospital, Huddinge, Sweden

### I GENERAL HORMONAL BACKGROUND

By definition obesity implies an excess of adipose tissue, which is not an inert storage room for triglycerides but actually the largest hormonally active gland of the body (1). Fat cells are known to convert androstenedione to estrone (2,3). Increased concentrations of estrone in obesity may interfere with the feedback system to the hypothalmohypophysial axis, increasing the levels of gonadotropins and androgens (4). As a consequence anovulation may occur. Furthermore, in obesity a reduction in sex hormone-binding globulin (SHBG) concentrations is seen, and the end result is an increased concentration of biologically active free androgens.

Menstrual disturbances are frequent in obesity and may often be normalized after weight reduction (5–7). Several studies have demonstrated that with weight reduction various characteristics of the hormonal profile can be normalized. As early as the 1950s the relationship between obesity and menstrual disorders was reported (8). A particular clinical syndrome associated with obesity and anovulation is the polycystic ovarian syndrome (PCOS), characterized by anovulation, hyperandrogenism, insulin resistance, and altered gonadotropin secretion (9,10). Several investigations have analyzed the relationship between weight loss and menstrual function in PCOS, but often these designs have had clinical and methodological limitations. In some situations, appropriate endocrine characteristics have

not been available, and in others no proper control group has been included.

In the study of Guzick (11), on the other hand, a group of obese hyperandrogenic anovulatory women were studied in a prospective randomized controlled fashion before and after a weight loss of 16.2 kg. This weight loss resulted in a significant increase in SHBG, a significant reduction in non-SHBG testosterone levels, and resumed ovulation in two-thirds of these subjects. These changes appeared in spite of nonsignificant reductions in fasting insulin concentrations and LH and FSH concentration characteristics.

The positive effects of weight reduction in obese women with PCOS are underscored by a study of Hamilton-Fairley et al. (12). These authors suggest that all overweight women—whether with PCOS or not—should be advised to lose weight before attempted conception in order to improve their chances of a successful outcome, and furthermore that PCOS women requiring gonadotropin treatment should consider weight loss before treatment to improve their chances of a successful pregnancy.

### II OBESITY AFTER PREGNANCY

It is common clinical experience that many overweight women report that each pregnancy has resulted in weight retention after delivery. Since pregnancy can in

fact be viewed as an example of weight cycling, increased interest has been focused on the behavioral and metabolic consequences of such repeated body weight cycling (13). Generally, weight cycles have been caused by initial weight loss during dieting programs with subsequent regains after relapse. The weight increase and subsequent fall during pregnancy constitute an interesting biological and "normal" cause of such reversed weight cycling.

Over the years interest has been focused on the possible role of repeated changes in body weight as a risk factor for coronary heart disease and all-cause mortality (14). When pregnancy-associated weight changes in terms of weight cycling and risk have been discussed, this has mainly been in normal-weight women and in relation to the fat distribution pattern (13).

As part of the Stockholm Pregnancy and Weight Development Study, a retrospective pilot study to obtain an impression of the role of pregnancy on body weight development in severely obese women was carried out (15). Seventy-three percent of these women (83/113) retained >10 kg in association with the pregnancy period and up to 1 year after delivery. Although it has been well documented that the body weight of women increases with parity and that many women have a higher body weight in the beginning of a subsequent pregnancy than in the previous one (16), there is little information concerning the importance of pregnancies in the development of obesity.

Several methodological questions may be raised regarding the validity of the self-reported data and the retrospective design of such studies. For some women, their pregnancies were certainly many years behind them, and it can be argued that memory must have been uncertain. However, most women do indeed remember their pregnancy-associated weight changes quite well. From these data it seems reasonable to assume that for many women, pregnancy has actually resulted in pronounced and sustained weight gain.

### III WEIGHT DEVELOPMENT AND PREGNANCY

Maternal weight development can vary to a very great extent and still be compatible with healthy pregnancy outcomes, which makes rigid recommendations meaningless. As reviewed by Johnson (17), weight loss during pregnancy as well as weight increases up to more than 23 kg may result in quite normal birth outcomes. Some factors affecting variation in weight gain are maternal characteristics such as age, prepregnancy weight,

parity, multiple pregnancies, ethnic origin, various aspects of socioeconomic status, drug abuse, and physical activity levels.

#### A Pregnancy, Weight, and Age

Mean body weight and the prevalence of obesity increase with pregnancy. Rookus et al. (18) reviewed the older literature on this issue (16,19–26) and concluded that (1) the cohort sizes varied from 49 to 35,556 deliveries; (2) age correction was seldom carried out; (3) prepregnancy weight was generally not well measured; and (4) the timing of the postpartum weight measurement varied from 4 to 24 months.

In a later extensive review by Harris (27), the general outcome of this literature was summarized as follows: 90% of all studies reviewed found a body weight greater after pregnancy than before (by 0.2–10.6 kg). However, only 3/71 studies in her review (18,28,29) complied with the following quality criteria:

1. Accurate measurements of body weight from conception and onwards must be obtained.
2. Sufficient time for weight lost after delivery must be allowed.
3. The parallel effect of ageing during pregnancy and follow-up must be accounted for.

In this subgroup (18,28,29) the average "cost" of a pregnancy was 0.9–3.3 kg. These differences in weight gain became slightly smaller (0.4–3.0 kg) after control for several sociobehavioral confounders. Thus in the literature it is generally rare that factors such as age, height, education, parity, giving up work, smoking habits, prepregnant weight and activity, alcohol consumption, marital status, morbidity, and dieting behavior obviously of importance in evaluating the role of physical activity, are accounted for (27). This evaluation is further complicated by the fact that changes of these confounders may take place in different ways and during various phases of the entire pregnancy period.

Since body weight also increases with age in the fertile age groups, it has been necessary to analyze weight increase, parity, and age separately. Such studies demonstrate that the weight increase associated with pregnancy is age independent. The relationship between body weight development and parity can be illustrated by Figure 1, derived from a Finnish study (30).

Body weight increases with age, whether women have children or not. Figure 2, based on a representative sample of the entire Swedish adult female population, is a cross-sectional example of the increase in BMI with age, more pronounced in women than in men. It should

**Figure 1** Relationship between body weight and parity. (From Ref. 30.)

be kept in mind that the basal metabolic rate typically decreases by  $\sim 1\%$  per year. For an individual who maintains an identical lifestyle with regard to eating habits and exercise, this implies a weight increase of about 3-4 kg per 10 years, which could possibly be regarded as "biological."

The average of reported weight increases with pregnancies thus range from 0.4 to 3.0 kg compared with prepregnancy weights (18). However, as many authors point out, there are several methodological complications that have to be taken into account, when these data are evaluated:

1. Women generally do not have recorded weight data at the time of conception. Initial body weight information is hence uncertain.

2. Weight increase during pregnancy consists of several components such as the weight of the fetus, the weight of placenta, amniotic fluid and the enlarged uterus, the whole-body water retention caused by the pregnancy, and finally the adipose tissue increase of the mother (31) (Table 1). For obvious technical and ethical reasons it is not possible to analyze all of these compartments in larger studies.

3. There is the methodological question to consider as when to determine postpregnancy body weight. Many women may change their weight during a considerable period of time after delivery. If the weight measurement is taken soon after delivery, this figure may not be representative of the entire weight development associated with the pregnancy as such. If, on the other hand, the weight after delivery is recorded at a late stage, numerous other life changes may have taken part, not primarily related to the pregnancy and delivery. In women in the active child-producing ages, some will be pregnant again, if the time span measurement is taken to 1 year after delivery.

Generally, a mean weight increase of 12.5 kg is considered normal during an entire pregnancy. In different studies reported by Ash et al. (32), the mean increase has ranged between 10.7 and 15.2 kg. In developing countries the weight increase for obvious reasons is considerably lower. Of the total weight increase a certain proportion consists of maternal adipose tissue,  $\sim 3$ -6 kg. This adipose tissue storage occurs mainly during the first two trimesters. From a nutritional point of view it seems reasonable to assume that the adipose tissue storage during pregnancy provides energy for the child during the lactation period.

**Figure 2** Mean BMI in different Swedish age groups. (From Ref. 95.)

**Table 1** Weight Increase (Including Fluid Retention) in Various Tissues at Full Term

|                            | Weight (g) | Fluid weight (g) |
|----------------------------|------------|------------------|
| Fetus                      | 3300       | 2340             |
| Placenta                   | 650        | 540              |
| Amniotic fluid             | 800        | 790              |
| Uterus                     | 900        | 740              |
| Mammary glands             | 400        | 300              |
| Blood                      | 1300       | 1100             |
| Extracellular fluid        | 1200       | 1200             |
| Other tissues (mainly fat) | 3950       | 1000             |
| Total                      | 12,500     | 8010             |

## B Menopause and Weight Development

A marked weight increase occurs at the time of menopause. However, it is not clear whether this is related to the loss of the regular menstruations or aging in itself has these effects on body weight development. Weight increase to the degree of overweight and even obesity at the time of menopause may have important health implications, since this is a part of the risk factor pattern associated with atherosclerotic manifestations. It has been demonstrated that with menopause there is an increase in the atherogenic lipoprotein profile (33,34).

In an analysis of the Healthy Women's Study (35), weight changes and the effect of weight change on coronary heart disease risk factors were analyzed prospectively. Four hundred eighty five women were studied when they were premenopausal and aged 42-50 years and then restudied 3 years later. During this time period the average weight gain was  $2.3 \pm 4.2$  kg, but there were no significant differences in weight gain of women who remained premenopausal and those who had a natural menopause. The weight gain observed was significantly associated with increases in conventional risk factors for coronary heart disease. However, it was not possible to predict who would gain weight based on the variables at entry to the study.

During the perimenopausal transition there is not only an increase in body weight but also a redistribution of adipose tissue with an increase in waist circumference and upper-body fat (36). This shift is also related to the change in carbohydrate metabolism (35).

The data from the Healthy Women's Study underscore the fact that much more information is needed concerning the effects of menopause on body weight development. Of particular interest for the future development are studies that are longitudinal and include various populations, since most previous work has almost exclusively been done in whites. It is of interest to note that a prospective study of Pima Indian women at the time of menopause found no changes in body weight with menopause and also no changes in lipoprotein levels (37).

## C Energy Metabolism During Pregnancy

It is obvious that nutrient and energy intake should match maternal and fetal requirements in order to ensure an optimal outcome of a pregnancy. Maternal weight gain has been used as an indicator for nutritional status, and several studies have demonstrated that the weight gain is positively related with birth weight up to a

certain weight level. Excessive weight gain during pregnancy is a clear risk for future development of obesity, and high weight gain during pregnancy is furthermore a risk factor associated with toxemia although it is likely that the toxemia of pregnancy in this case is rather the cause than the effect.

The body weight increase of the pregnant woman constitutes the sum of several tissues (31). To determine the true energy costs of a pregnancy, longitudinal studies are essential, since interindividual variations are marked. During recent years several such longitudinal studies have been published. In general they describe a similar pattern: in developing countries the energy costs of the pregnancy are low but increases in countries in the Western world. In all studies, however, the observed changes in energy intake over the entire pregnancy seem insufficient to meet the energy costs of the total pregnancy. This has led several researchers to speculate that substantial energy savings must occur during pregnancy.

The weakening of the relationship between gestational weight gain and birth weight with increasing body mass index of the woman suggests that in heavy women the energy supplies are generally sufficient, whereas in undernourished women the development of the fetus is more dependent on the state of the maternal nutrition. Thus different recommendations for suggested weight increase throughout a pregnancy may be appropriate in thin women. Energy balance is less of a problem in overweight women, and recommendations in this group would be adjusted accordingly.

## D Energy Metabolism During Lactation

Energy requirements for an entire pregnancy are ~80,000 kcal or ~300 calories per day covering the needs for fetal growth and adipose tissue storage. Lactation has been assumed to facilitate weight loss after delivery, particularly if the period of lactation exceeds 2 months. Lactation has been calculated to increase the energy requirements by 500 kcal/d, which also takes into account that production of milk is an energy requiring process.

After delivery and during lactation, the role of maternal body fat mobilization could theoretically be a matter of conflicting interests. Excessive maternal body fat mobilization during lactation could increase the concentration of fat-soluble contaminants in the breast milk, which theoretically could have adverse health effects for a baby relying entirely on breast feeding. This is a research area that should be addressed in future

research. A target group for such research would be older mothers for several reasons. First, body weight increases with age and parity and such mothers could be more inclined to try to use complete breast feeding as help to revert to prepregnancy body weight levels. On the other hand, since environmental contaminants accumulate with time in adipose tissue, the fat stores of these older mothers might contain a higher concentration of such toxins and thus pose a larger risk for the infant. It has recently been reported that PCB trace element concentrations increase in the circulation after weight loss, but the possible clinical significance of that finding is unclear (38).

Studies by Rebuffé-Scrive and others have demonstrated that the characteristics of the adipose tissue change dramatically during pregnancy [39]. Adipose tissue lipolysis in the femoral region is limited during pregnancy, but can be easily stimulated hormonally during lactation. This seems to be a functional adaptation of the adipose tissue to the needs of the mother and the child.

However, the relationships between lactation, energy needs, and energy balance are not fully clarified. In some studies no difference in energy intake was found between lactating and nonlactating women. Other studies suggest that lactation plays a minor roll in weight reduction after delivery (18,40). In the Stockholm Pregnancy and Weight Development Study a minor roll of lactation on body weight regulation was demonstrated (25,41).

From a theoretical point of view weight changes after delivery could also depend on changes in basal metabolic rates. Prentice and Prentice (42) identified three hypothetical mechanisms which could explain the lack of weight loss after delivery: (1) reduced basal metabolism; (2) impaired thermogenesis; and (3) reduced physical activity. These mechanisms could account for reduction in energy requirements of up to 240 calories per day. Thus, it is possible that the energy need during lactation can be provided from different sources such as a combination of an increased energy intake, utilization of adipose tissue in storage, and a metabolic adaption.

These hypotheses, however, were not supported by a Dutch study. Spaaij et al. (43–45) studied prospectively various aspect of energy metabolism in 27 women, who were monitored repeatedly before pregnancy, during each trimester and during lactation. Three different aspects of such energy savings were analyzed: the possibility that the thermic effect of meals is reduced during pregnancy; the possibility that work efficiency improves during pregnancy; and finally the

alternative that during lactation the metabolic efficiency is altered.

No changes were observed of any of these three factors, possibly explaining the discrepancy between energy intake and the energy costs of a pregnancy. Therefore the Dutch group reassessed the extra energy needs during pregnancy and concluded that such extra needs may be met by an increase in energy intake but also by substantial behavioral adaptations. As an example, energy savings by reduced physical activity seem to be higher than earlier estimates. The large variations between subjects regarding both energy intake and energy expenditure lead the Dutch group to suggest that energy intake recommendations for well-nourished pregnant women have little value. Since no metabolic adaptations seemed to appear, Spaaij et al. conclude that underestimation of the energy savings by reduced physical activity probably explain the imbalance noted between energy input and output.

In a similar design a Swedish group has monitored energy expenditure of healthy women during pregnancy and lactation (46). In these studies, 23 healthy, normal-weight women were monitored as regards body composition and energy metabolism before a planned pregnancy, and then immediately after delivery and 2 months and 6 months postpartum. Only minor changes were found with a slight increase in resting metabolic rate during lactation and a small energy intake increase during the lactation period of  $280 \pm 440$  calories per day. In this group the main fat gain during pregnancy was  $5.8 \pm 4.2$  kg, which was not lost during the first 2 months of lactation but disappeared partly between 2 and 6 months after delivery. These authors underscore the importance of methodological problems in estimating body composition, and suggest that a lack of correlation between changes in body weight and body fat during early pregnancy might be explained by changes in the degree of hydration of the body. Regarding physical activity, the Swedish study suggests that there was a tendency to increased physical activity during early pregnancy (47). The Swedish study supports previous work that lactation does not affect the metabolic efficiency but proposes that with extremely accurate methods it might still be possible to detect minor such differences.

That not only behavioral but also genetic factors at least partly explain weight development after delivery was illustrated in a study by Harris et al. (48). That group monitored women who had given birth and been followed in a project database for up to 2.5 years. They confirmed that body weight dissatisfaction was associ-

ated with increased likelihood for weight retention, but that women who selected larger silhouettes in a questionnaire as proxy indicators of the body shapes of their mothers were themselves also more likely to maintain more body weight (48).

#### IV STOCKHOLM PREGNANCY AND WEIGHT DEVELOPMENT STUDY

To further analyze the relationships between body weight, weight development, pregnancy, lactation, sociodemographic factors, and weight retention, the Stockholm Pregnancy and Weight Development Study was started in the mid-1980s (25,41,49). It is now reopened as "SPAWN" for the study of long-term effects of previous pregnancies on weight history. The study was designed as a combination of retrospective and pro-spective parts. Women who were invited to participate represented a mixture of the southern Stockholm metropolitan area, the Stockholm suburbs, and the countryside. A total of 1423 women completed the entire study. Detailed analyses failed to reveal that the salient results of the study could be explained by a selective dropout mechanism.

From the obstetric records and the questionnaires administered at follow-up, data were computed regarding body weight, age, parity, nationality, occupation, living site, marital status, smoking habits, contraceptive practices, duration of lactation and lactation intensity, weight-losing practices, return to salaried work, eating, and exercise habit. The prepregnancy weight was accepted from the women's own reports.

The validity of the prepregnancy reported weight constitutes an important methodological problem. We compared the data with results obtained from a subgroup of 49 women, who were excluded from the 12-month follow-up because of a new pregnancy. This gave us an unforeseen opportunity to compare their reported weight with the weight that was recorded as the starting level for their next pregnancy. The reported mean weight was 0.92 kg lower at the onset of pregnancy than the latest recorded weight obtained under our study conditions. The mean weight loss between 6 and 12 months after delivery was calculated to 0.12 kg from data from the entire study. If we subtract this weight from 0.92 kg, we can estimate that these women have reported an initial body weight at onset of the new pregnancy which was on average 0.8 kg lower than their true body weight.

These results fit reasonably well with studies of a group of Swedish women where true prepregnancy

weight data could be obtained since these women were studied and weighed at a time when their intrauterine device was removed before a planned pregnancy (50).

#### A Weight After Delivery

The mean weight increase 1 year after delivery compared to the reported weight at the time of conception was 1.5 kg (Fig. 3). When we corrected for the estimated underreporting of the weight at conception from our parallel studies (0.8 kg plus the estimated mean weight increase with time 0.2 kg), the net mean weight increase induced by a pregnancy was calculated at 0.5 kg. However, the range was very wide: 1.5% of the women had a mean weight retention of at least 10 kg, and 13% had a weight retention between 5 and 10 kg. The majority (56%) had a weight retention of up to 5 kg. Thirty percent of the women lost weight. The wide weight change distribution one year after delivery is shown in Figure 4.

Table 2 summarizes characteristics of weight development after delivery. The correlations of established behaviors at baseline and changes in behavior with weight change overall exhibited very low *r* values. Women with > 5 kg weight retention differed from the other women in several respects. Whereas women with a small net increase in weight lost a mean of 2.3 kg between 2.5 and 12 months after delivery, women with larger weight retention increased 0.4 kg during the same time period. Those who retained more weight:

1. Had a larger initial body weight.
2. Had gained more in weight during pregnancy.
3. Were lactating to a lesser extent.
4. Stopped smoking during pregnancy more often.

**Figure 3** Body weight changes in 1423 Swedish women from conception until 12 months postpartum (kg  $\pm$  SD). Dashed line shows mean prepregnancy weight. (From Ref. 25.)

**Figure 4** Distribution of weight changes from conception until 12 months postpartum in 1423 Swedish women with different prepregnancy BMI values. (From Ref. 25.)

We also found a less well structured eating pattern of dietary habits before, during, and after pregnancy (Fig. 5) (41). Those women who retained more body weight reported that their energy intake had increased after delivery, since they ate larger portions and snacked more frequently. They had less regular eating habits and did not eat breakfast or lunch as regularly as women who retained less weight. Age and parity did not differ between women who retained  $>5$  kg and those who retained less.

## B Lifestyle Trends and Lactation

Figure 6 demonstrates that the weight increase during the first trimester is already predictive of future overall weight increase. This could have preventive implications and suggests that life style recommendations concerning optimal weight increase should start early during pregnancy. In Stockholm, weight retention increased only slightly with age and not with parity. Women who gave up smoking when they became pregnant increased more than others; 45% of these women retained  $>5$  kg.

Interestingly enough, lactation played a small roll for weight control after delivery. Although there was a significant relationship between a lactation score and weight retention, the  $r$  value was low ( $r = .05$ ,  $P < .01$ ) (Fig. 7). However, there was a difference with time, in that women with a high lactation score lost more weight during the first half year after delivery. Toward the end of the year, the differences between the groups were limited. Only in a small subset of subjects, those who had been lactating for a whole year, was a significant reduction of body weight compared to prepregnancy weight found.

The lack of importance of lactation for weight loss after delivery may seem surprising, but has been

**Table 2** Characteristics of Weight Development After Pregnancy

|  |                       |

Figure 6 The Stockholm Pregnancy and Weight Development Study. Weight loss in kg from 2.5 to 12 months postpartum in groups with different lactation scores. Statistically significant differences from score 0-9 and 10-19 shown as \* $P < .05$  and \*\* $P < .01$ . (From Ref. 25.)

reported previously by Rookus (18) and was also described by others, as cited in her review.

In clinical practice, women are often instructed to try to breast-feed as much as possible to revert to normal weight after delivery. This seems logical, since a full lactation requires  $\sim 500$  calories per day, which may constitute about 20-25% of the daily energy requirement of women in this age group. However, it is possi-

Figure 7 Trimester-related mean weight increase in women with different total weight increase. (From Ref. 96.)

ble that the changes in eating behavior and lifestyle affect women in such a way that they only use their adipose tissue storage when food is not readily available, as has been suggested by Prentice (42).

Questions regarding eating habits, physical activity, and lifestyle revealed that there was a tendency for women who retain more weight to develop a more sedentary and irregular lifestyle. This can, of course, be explained by the new social situation and the lack of opportunities to engage in outdoor physical activities, when the care of the newborn has become a first priority. Women who had received dietary guidance during pregnancy did not have a more favorable weight outcome than those who did not receive such support.

In summary, the metabolic cost of an entire pregnancy seems to be extremely flexible and is influenced by numerous factors, such as maternal prepregnancy nutritional status, energy intake during pregnancy, fetal size, and a combination of these factors. Metabolic adaption may possibly occur to spare some energy for fetal growth, should this be insufficient.

### C Maternal Body Weight and Birth Weight

The definition of optimal weight gain during pregnancy remains controversial. The old saying is that a pregnant woman should “eat for two.” On the other hand, in affluent societies where overweight is more of a problem than starvation, it is important that the dietary recommendations not expose pregnant vulnerable women to the risk of subsequently developing an excess of fat that they may later have great difficulty in losing. The safety of the newborn is one basic concern, and a low birth weight constitutes a well-known risk, but “eating for two” must be balanced against the adverse effects of overweight and obesity.

A linear relationship has been reported by some authors between birth weight and maternal pregnancy weight gain at all levels of pregnancy weight (23,51,52). Others suggest that as maternal weight increases, the infant's birth weight will increase proportionately less (53–56). As part of the data analyses of the Stockholm Pregnancy and Weight Development Study, the relationships between initial maternal body weight, weight development during pregnancy, and birth weights were studied (57). The birth weight increased with maternal pregnancy weight gain minus birth weight in each group. When divided by quartiles, children of mothers in the two groups with the highest net weight increase were significantly heavier than those of the two groups that increased <10 kg. However, in women who had a net weight gain exceeding 10 kg, no further significant

birth weight increase with maternal weight was found. For the total material the correlation between net maternal weight gain and birth weight was  $r = .17$  ( $P < .001$ ). Net weight increase (defined as maternal weight increase minus birth weight) explained only 3.0% of the variation in birth weight. When initial body weight was added, these two factors together explained 5.0% of the variation in birth weight.

Numerous factors, such as paternal and maternal heredity, maternal prepregnancy weight, nutrition, and several hormonal factors, ultimately determine the infant's birth weight (58). The Stockholm study is confined to total maternal body weight, and it should be borne in mind that lean body mass rather adipose tissue seems to be the important determinant of birth weight. Our data support the concept that birth weight increases with maternal weight up to a certain level, and then levels off.

### V AMERICAN IOM RECOMMENDATIONS

During the past 50 years recommendations for healthy pregnancy weight development have been controversial in many parts of the world. The initial concern was mainly focused on safety for mother and infant. The emerging obesity epidemic, however, has made it more and more important to scrutinize to what extent an extensive and physiologically unnecessary weight gain during pregnancy could be an unfortunate lead into overweight and obesity of the mother.

In countries with low socioeconomic status or with ethnic subgroups containing such individuals, it is clear that a low weight gain during pregnancy is an indicator of poverty, malnourishment, and future risk for high infant mortality, disability, and even mental retardation.

In the United States, the Institute of Medicine (IOM) issued recommendations in 1990, which were more liberal than before and hence caused considerable discussion. Some experts even claimed that these IOM recommendations would not improve perinatal outcome and would have negative consequences for both infant and mother: the liberal weight increase recommended ranges advocated by the IOM would produce overgrown newborns, result in an increased frequency of cesarean sections, and eventually also trigger obesity in the mothers.

Abrams et al. (59) have recently reviewed all studies that examined fetal and maternal outcome. They conclude that there is an impressive body of evidence indicating that weight gains within IOM recommendations are indeed associated with better pregnancy out-

come but found no evidence that such pregnancy weight gain is a course of substantive postpartum weight retention. The authors are, however, anxious to point out that the studies on which these conclusions are based are observational and not experimental. They note that maternal weight gain alone may not be a very helpful predictor of poor pregnancy outcome and that a good pregnancy outcome can be associated with a wide variety of weight development patterns throughout pregnancy. Furthermore, these studies are based on data from an American population. Seen the other way around, it is clear that many women, seeking professional help for their overweight and obesity, report their pregnancies as having been major events in their overweight development.

## VI PREGNANCY, WEIGHT, AND SMOKING

Smoking affects body weight. Generally, smoking increases the basal metabolic rate by ~10% (60), and smokers are relatively lean (61,62). The weight development pattern in pregnancy is confounded by the fact that many smoking women give up this habit when they learn of their pregnancy.

Smoking mothers seem to gain ~13% less per week than nonsmokers (63). In this study from Australia, "reformed smokers," who decided to quit when they learned of their pregnancy, had the highest weekly weight gain of all groups. Our Stockholm data show similar results, both with a high pregnancy weight gain and also with higher weight retention than in those who never smoked or who continued (25). However, these results are not in agreement with all other studies. In the large Ontario Perinatal Mortality Study of 31,788 women smoking habits were unrelated to maternal weight gain distribution (64).

## VII OBESITY, WEIGHT GAIN, AND PREGNANCY COMPLICATIONS

Obesity is considered a risk factor in pregnancy, but knowledge of the relation of the degree of maternal obesity to risk for specific complications and pregnancy outcome remains unclear (65–69). There are several methodological reasons for the lack of precise knowledge about these interrelationships, such as exact definitions of obesity and adequate control groups. In a study from Chile, a group of obese pregnant women were compared with a group matched for age and parity but with normal weight (70). Differences between the two groups were found with regard to gestational hyper-

tension, inadequate pregnancy weight gain, cesarean section frequency, postpartum infections and, large-for-gestational-age infants. No significant increase in the incidence of diabetes, toximia, breech presentation, postpartum hemorrhage, infant morbidity, or lactational failure was noted in the obese women. The authors conclude that although obesity is an important risk factor, methodological aspects of previous studies may have magnified the severity of the problem.

This view is also supported by later studies. In a case control study from California with a similar design, it was shown that massively obese pregnant women were significantly more likely to have a multitude of adverse effects (71). The frequency of cesarean section was doubled, and child malformation or growth retardation were much more prevalent. However, when obese women with diabetes and/or hypertension antedating pregnancy were excluded from the analyses, no statistically significant differences in perinatal outcome persisted. These authors thus conclude that although massively obese pregnant women are at high risk for adverse perinatal outcome, these risks are more related to preexisting morbid conditions than to obesity in itself.

In the Stockholm study the overall frequency of cesarean sections was 12%. There was a tendency, although statistically nonsignificant ( $\chi^2=2.62$ , n.s.), toward a higher frequency of sections in mothers with higher initial BMI values. The mean initial BMI for vaginal deliveries was 21.5 vis-à-vis 21.8 kg/m<sup>2</sup> for cesarean sections.

The frequency of cesarean sections in all women in this study is close to the available Swedish average figure of 12.4%, reported from the corresponding time period. The problem concerning an increased need for cesarean sections in obese mothers is not clear (72).

## VIII DIABETES, OBESITY, FAT DISTRIBUTION, AND PREGNANCY

Maternal obesity represents a significant risk factor for the development of gestational diabetes mellitus and subsequent adult-onset diabetes. Obesity in itself is associated with major alterations in carbohydrate metabolism such as insulin resistance and hyperinsulinemia, eventually resulting in hyperglycemia (73). Not only is the degree of overweight important for the likelihood to develop diabetes, but also body fat distribution with upper-body obesity are more important risk factors than generalized increase in body fat (74). In a study of pregnant women with various types of fat

distribution, repeated oral glucose tolerance tests were carried out during each trimester and postpartum (75). This study demonstrates that in upper-body obese women, pathological carbohydrate metabolism became apparent during the second trimester and that a significant relationship between waist/hip ratio and glucose levels, as well as insulin areas were found in late pregnancy in all obese subjects.

## **IX BODY FAT DISTRIBUTION AND CONCEPTION CAPACITY**

Although obesity is common among multiparous women, it is possible that this weight increase is the result of multiple pregnancies rather than a prerequisite for conception. From ancient history the obese female has been considered a symbol of fertility. In some cultures it has been believed that obese women are more likely to bear twins. Although it is well known that underweight women have an impaired capacity to conceive, the effects of overweight and obesity on female fecundity have been less studied. A shift of the hormonal balance toward increased androgenicity in association with an abdominal obesity has been found to lead to menstrual disorders (5,76).

### **A Weight and Infertility**

A moderate degree of overweight may affect the reproductive capacity significantly. In a case control study of body mass index and ovulatory infertility, 597 white infertile women with ovulatory dysfunction were compared with 1695 primiparous control women (77). The study demonstrated an increased risk for primary ovulatory infertility already in women with a body mass index of 27 kg/m<sup>2</sup> or greater. At BMI above 25 kg/m<sup>2</sup>, the risk of ovulatory infertility had almost doubled.

Women admitted to an in vitro fertilization unit provide a unique opportunity to study determinants of fecundity while controlling for several other confounders related to conception. In a Dutch study the probability of conception after insemination was studied in 500 women (78). The main reasons for artificial insemination were infertility or subfertility of the partner with azoospermia or oligospermia, respectively. The youngest woman was 20 years old; only a few women were above age 40. Two hundred sixty women reported regular smoking habits. As expected, the women were less likely to conceive with higher ages ( $P < .05$ ). The study demonstrated that a 0.1-unit increase in waist-hip ratio was associated with a 30% decrease in probability of

conception per cycle. These data were adjusted for age, overall fatness, clinical indication for insemination, cycle characteristics, smoking habits, and parity. The main finding of this study is that an increase in waist-hip ratio suggesting increased androgenicity was associated with a reduced fecundity. In obese women weight loss often normalizes the regular menstrual cycles and sex hormone concentrations (8,79). This indicates that obesity itself rather than a primary endocrine dysfunction is the cause of the reproductive insufficiency.

### **B Diabetes, Weight, and Fertility**

Type 2 diabetes is associated with obesity as well as with pregnancy. The association between parity and type 2 diabetes has been studied in several populations where either no relationship or a positive association generally has been described. On the other hand, infertility has been associated with a high risk for type 2 diabetes. The complex interrelationship between these factors has recently been studied among Pima Indian women (80). In a longitudinal epidemiological study of diabetes the role of parity and obesity was analyzed after control for age. This study demonstrates that Pima women who had never been pregnant had a higher prevalence of type 2 diabetes but also a higher BMI than women who had been pregnant. To a certain extent this difference could be accounted for by a higher degree of obesity. Possibly high estrogen concentrations could explain the oligomenorrhea or amenorrhea and thus the decreased fertility through a negative feedback mechanism at the hypothalamopituitary level (81).

The fact that there is no consistent relationship between parity and type 2 diabetes may be due to a combination of two effects counteracting each other. On the one hand, pregnancy may be diabetogenic by leading to an accelerated and sustained weight gain that could precipitate a clinically manifest form of type 2 diabetes. On the other hand, it is possible that women of low fertility run a higher risk of developing type 2 diabetes because of a common factor, or several common factors, contributing to both these conditions.

## **X PREGNANCY, BODY WEIGHT DEVELOPMENT, AND PHYSICAL ACTIVITY**

Physical activity is obviously an important determinant of weight development, even in pregnancy (82). A retrospective analysis of the literature, mainly based on an extended Medline search and the Pregnancy and

Childbirth Database (Cochrane), was recently carried out to elucidate the importance of physical activity in determining weight gain characteristics (83).

Several methodological matters complicate the interpretation of the interrelationships: generally body weight and not fat has been measured; sociobehavioral confounders have rarely been accounted for; and the time frame to determine the effect of pregnancy on later weight development has been highly variable. Most studies reviewed concentrate on the role of physical activity, such as recreational activity and sports, on the safety of the pregnant mother and the fetus. Again, less emphasis is put on the potential role of physical activity to prevent or restrict weight retention in obesity-prone women. Advice is general and mostly obvious ("boxing as exercise during pregnancy is discouraged. . .").

One of the few studies addressing the question of recreational exercise on pregnancy weight gain and subcutaneous fat deposition is the paper by Clapp (84). This study thus demonstrates that well-educated, non-smoking, highly motivated women who maintained a balanced diet and were nonobese before pregnancy, accumulated slightly less fat in the last trimester when exercising. Self-selection, nonquantification of the amount exercised, and a very selective group of women limit the possibility of extrapolating these results to the population at risk, for whom pregnancy is major trigger for weight retention and subsequent obesity.

## **XI SOCIOECONOMIC AND ETHNIC ASPECTS ON PREGNANCY-RELATED WEIGHT GAIN**

Women with low education and low income are at increased risk of gaining weight and becoming overweight. Furthermore, there seem to be differences in race. Over a 10-year period the overall mean weight gain for black women was 36% higher than for white women (85). Parker and Abrams (86) have analyzed the 1988 National Maternal and Infant Health Survey to study whether this additional increase in body weight among black women could be explained by factors relating to pregnancy. They found that black mothers were twice as likely to retain at least 20 lb as white mothers (adjusted odds ratio 2.20, 95% CI 1.50-3.22), but that this black-white difference could not be explained by differences in socioeconomic status. There were other differences in the weight increase pattern. Weight attention was more likely to occur in white women who were unmarried,

whereas weight retention in black mothers was more associated with high parity. These data suggest that it may be necessary to develop population-specific strategies in helping mothers to return to their prepregnancy body weight.

## **XII WEIGHT DEVELOPMENT IN PREGNANT ADOLESCENTS**

Since maternal weight gain is an important and manageable determinant of infant birth weight among adolescents, some studies have addressed factors related to weight gain in young women. Generally, the women studied have been poor and with numerous psychosocial problems including drug abuse. Stevens-Simon (87) studied pregnant black teenager (87). The group was divided into three different weight gain subgroups. Slow weight gain was associated with a lower quality of food intake. Teenagers who gained more weight during their pregnancies were more compliant with prenatal visits, but also reported more depressive symptoms and more alcohol consumption. An important finding was the substantial variability in the amount of weight gain, ranging from 1.8 to 27.9 kg with a mean weight increase of  $14.3 \pm 6.0$  kg (SD). This study suggests that proper nutritional care in this group of young women may be an effective method to promote optimal gestational weight gain. In the analysis of the 99 pregnant young women (88), most were poor but with an ethnic variability. The authors had anticipated that negative attitudes toward pregnancy weight gain would be more common among these young women and that such attitudes would adversely affect an optimal adolescent maternal weight gain. These teenagers were studied by means of a weight gain attitude scale as well as several other determinants of nutritional status, dietary and health habits, and social history. Surprisingly enough, the authors demonstrated that these young women were not more concerned about staying slim than older pregnant adolescents and adults. Negative weight gain attitudes were more commonly found among heavy and depressed adolescents and those who did not have a family support.

The examples of weight gain-related factors in adolescents given above relate to the problems in the United States. It is reasonable to believe that the situation will be quite different in other cultures, where pregnancy early in the life of a young woman might be considered a normal life event or in societies where the attitude to abortion in pregnant teenagers is different. For this

special group of women, appropriate food supplies may be one simple method to ensure optimal weight gain and good pregnancy outcome.

### XIII WEIGHT GAIN DURING TWIN PREGNANCIES

Few data are available concerning the optimal weight development during twin gestation. Pederson et al. (89) addressed this question in a retrospective evaluation of the outcome of 217 twin pregnancies. The optimal outcome was associated with a mean weight gain of ~20 kg. These authors were able to construct a weight gain curve for twin gestation, which was compared with the standard weight development curve for singleton pregnancies. During the first half of the pregnancy, curves for singleton and twin pregnancies were similar, after which a more marked increase was seen in twin pregnancies during the second trimester and until term. It is still unknown whether multiple pregnancies require different nutritional needs, but until such data are available it seems practical to use weight gain as a proxy measure of the nutritional status of the mother and her twin fetuses.

### XIV GENERAL CLINICAL CONSEQUENCES

Since little weight loss advice is generally offered women after delivery, the results of a prospective, controlled randomized study of the effects of a recent correspondence course are of interest (90). Women taking the 6-month course lost significantly more weight (7.8 vs. 4.9 kg,  $P = .03$ ) than controls. The study indicates that with creativity, weight loss after delivery can be achieved at low cost and with surprising efficiency.

Recent diagnostic and pharmacologic developments have focused renewed attention on polycystic ovary syndrome as an important cause for obesity-associated infertility (91), but subfertility may also occur in obese women who do not suffer from this syndrome. Among choices women can make for themselves to improve their general chances of conceiving, body weight control and proper eating habits are important (92).

For anovulatory women with a weight problem, a general program promoting a better lifestyle with an improved self-esteem has been found to be surprisingly effective in not only improving their quality of life (93) but also their subsequent chances of conceiving. The women were treated with a standard program including diet, exercise, and behavioral modification. In this un-

controlled study the ensuing mean weight loss of 6.3 kg resulted in a marked improvement of the hormonal profile (reductions in testosterone and insulin concentrations) and also conception in 11/13 women, some even without further hormonal stimulation. In what seems an extension of that study, these Australian authors treated 37 obese women and after a mean weight loss of 6.2 kg, only six anxious to become pregnant had not conceived within 36 months. This study is open and uncontrolled, but it may be argued that studies of this kind will probably be difficult to design as proper randomized, prospective controlled trials for several reasons (94).

## Physical Activity, Obesity, and Health Outcomes

The Cooper Institute, Dallas, Texas, U.S.A.

### I INTRODUCTION

As documented by recent national and international guidelines, obesity is a significant public health problem (1,2). The prevalence of overweight and obesity is increasing in many countries around the world. In the United States it is estimated that at least 55% of adults are overweight or obese (defined as a body mass index [BMI]  $\geq 25$  kg/m<sup>2</sup>), and according to recent surveys, the prevalence of obesity (BMI  $\geq 30$  kg/m<sup>2</sup>) in the United States increased from 12% to 19.8% between 1991 and 2000 (1,3,4). Low levels of energy expenditure from physical activity are likely a major contributing factor to the rapid increase in the prevalence of obesity (5–7). Although there are no direct data, it seems probable that a decline in energy expenditure has taken place due to obvious changes in occupational- and household-related physical activity, as well as urban environments that are increasingly less conducive to leisure-time physical activity.

In the United States, the most recent data indicate that 29.2% of adults are inactive in their leisure time and 43.1% participate in some leisure-time activity but at levels too low to confer significant health benefits. Only 27.7% of U.S. adults are physically active at recommended levels (8,9). Compared with normal-weight and overweight adults, obese individuals are more likely to report being inactive (27.3%, 28%, and 37% respectively) (9). Cross-sectional and cohort studies suggest that differences in amounts of physical activity contrib-

ute to differences in body weight and body fatness and play an important role in whether obesity develops (10–13). A recent ecological review of secular trends suggests that the prevalence of obesity is more strongly related to decreases in energy expenditure than to increases in energy intake (14).

A large body of scientific evidence and consensus opinion indicates that physical activity is an essential element, along with dietary and behavioral modification, in the clinical strategy for weight management for patients who are overweight and obese (1,8,15). In recent years, professional and governmental bodies have provided expert consensus recommendations on physical activity for health promotion and disease prevention in all adults (8,16–18). The latest guidelines can be summarized as follows:

All adults should increase their regular physical activity to a level appropriate to their capacities, needs, and interests. The long-term goal is to accumulate 30 min or more of moderate-intensity physical activity (i.e., brisk walking, leisurely cycling, swimming, recreational sports, home repair, and yard work) on most, preferably all, days of the week. People who currently meet these recommended minimal standards may derive additional health and fitness benefits by becoming more physically active or including more vigorous activity.

The recommendation from the National Heart, Lung, and Blood Institute's Clinical Guidelines on the Identification, Evaluation, and Treatment of Overweight and Obesity in Adults for physical activity as

part of a comprehensive weight loss program is consistent with the above summary statement and is based on an evidence-based review of the scientific literature (1).

The purpose of this chapter is to review the current scientific evidence on the interrelationships among physical activity, obesity, and health outcomes. We will give particular attention to recent evidence-based consensus statements on physical activity and obesity. We also will review prospective observational studies from the Aerobics Center Longitudinal Study cohort and other investigations that stratify health outcomes based on both markers of body habitus and measures of cardiorespiratory fitness or physical activity. We will review evidence from randomized controlled trials (RCT) on the influence of exercise intervention on obesity-related disease risk factors and conclude the chapter with recommendations in the areas of research, public health, and clinical practice.

## II OBESITY AND HEALTH OUTCOMES

Obesity is associated with increased morbidity and mortality (1). The risk of death from all causes, cardiovascular disease (CVD), certain cancers, and other diseases increases throughout the range of moderate and severe overweight for both men and women in all age groups (1,19–21). Although a subject for debate, consensus opinion indicates that mortality rates begin to increase modestly with BMIs  $>25 \text{ kg/m}^2$  with more significant increases occurring in individuals with a BMI of  $30 \text{ kg/m}^2$  or higher (1,2,19,20). There are differences among racial groups in the pattern of the association between BMI and mortality (19). Some experts estimate that obesity is second only to cigarette smoking as a leading cause of death in the United States and is associated with  $\sim 300,000$  deaths per year among adults (22). Physical inactivity and poor dietary habits may be the main lifestyle factors contributing to the excess deaths associated with obesity (23,24). The contribution of obesity to increased morbidity and mortality appears to be independent of its influence on known risk factors, and this is particularly true for CVD (25,26). Overweight and obesity are directly related to an increased risk of several medical conditions including insulin resistance, glucose intolerance, type 2 diabetes mellitus, hypertension, dyslipidemia, and impaired physical function (1,27). There is strong evidence that weight loss in overweight and obese individuals reduces risk factors for diabetes and CVD (1).

Because of the health consequences of excess body fat, it is likely that the current epidemic of obesity will translate into increased prevalence of adverse health

outcomes (28). The total healthcare cost attributable to obesity and its comorbidities represents a substantial economic burden (1,29). Concerns about the rapidly rising rates of obesity and associated negative health outcomes have generated calls to action for significant changes in clinical intervention and public health policy (1,2,30). We believe that regular physical activity, because of its contribution to the regulation of energy balance, and, as we will review in this chapter, favorable effects on several of the comorbidities of obesity, must assume a primary role in both public health and clinical efforts to prevent and manage obesity and its associated comorbidities.

## III PHYSICAL ACTIVITY AND HEALTH OUTCOMES

A large body of scientific evidence and consensus opinion confirms that low levels of physical activity and cardiorespiratory fitness are associated with high rates of all-cause and cause-specific mortality across diverse population groups (8,16–18,31,32). Regular physical activity and moderate to high levels of cardiorespiratory fitness are associated with more favorable disease risk profiles and lower all-cause and CVD mortality (8,16, 33–35). The inverse association between physical activity or cardiorespiratory fitness and premature mortality is independent of changes in disease risk factors and other potentially confounding variables (36,37).

Based on a review of 42 prospective cohort studies, Lee and Skerrett concluded that there is clear evidence of an inverse dose-response relation between volume of physical activity (or level of physical fitness) and all-cause mortality rates (34). These studies suggest that physical activity resulting in an energy expenditure of  $\sim 1000 \text{ kcal/wk}$  is associated with a significant 20–30% reduction in risk of all-cause mortality (33,34). Evidence-based review also supports an inverse dose-response relation between physical activity and incidence and mortality rates from cardiovascular and coronary heart disease (CHD) (33,35). Available data indicate a beneficial effect of physical activity on incidence of colon cancer; however, the evidence is less conclusive for a reduction in risk for other types of cancer, such as cancers of the breast and prostate (33,38).

Physical activity and higher levels of cardiorespiratory fitness are associated with lower risk for type 2 diabetes, hypertension, weight gain, and functional limitations that often occur with aging (33,39–42). Activity and fitness are also associated with improvements in the plasma lipid profile and favorable alterations in coagu-

lation and hemostatic factors (33). Other benefits of physical activity include a reduced incidence of depressive illness and improved symptoms in individuals with mild to moderately severe depressive illness (33,43).

### A Aerobics Center Longitudinal Study

In this section, we provide a review of studies from the Aerobics Center Longitudinal Study (ACLS) cohort to describe in more detail evidence supporting a strong and independent effect of moderate to high levels of cardiorespiratory fitness on all-cause and CVD mortality in men and women (31,36,44). These studies also introduce preliminary evidence suggesting a protective effect of cardiorespiratory fitness on mortality independent of body mass.

The ACLS is a prospective observational study of patients between the ages of 30 and 83 examined at least once between 1970 and 1993 at the Cooper Clinic in Dallas, Texas. All participants undergo a thorough evaluation including a medical history, physical examination, anthropometry, blood chemistry, and a determination of cardiorespiratory fitness by a maximal exercise test on a treadmill. Each participant's level of cardiorespiratory fitness is based on age and maximal time on the treadmill. In this cohort, total treadmill time correlates highly ( $r = .92$ ) with measured  $\text{VO}_{2\text{max}}$  (45). The least fit 20% are classified as unfit, the next 40% are classified as moderately fit, and the top 40% as high fit. Anthropometric measures include BMI ( $\text{kg}/\text{m}^2$ ) calculated from directly measured height and weight, percent body fat determination by hydrostatic weight and/or sum of seven skinfold measurements, and waist circumference measured at the umbilicus. Mailed follow-up surveys and the National Death Index are used to determine morbidity and mortality endpoints.

In 1989, we published a report in which age-adjusted all-cause death rates were calculated across low, moderate, and high cardiorespiratory fitness categories in 10,224 men and 3120 women who were apparently healthy at baseline (31). The results demonstrated a strong and graded inverse association between cardiorespiratory fitness and mortality due to all causes, CVD, and cancer with the major difference in death rates observed in the moderately fit men and women when compared with those with low fitness. Although not specifically designed to examine the relationship among cardiorespiratory fitness, obesity, and mortality, this study provides preliminary evidence of a protective effect of moderate to high levels of cardiorespiratory fitness in overweight men and women. In this study, we found that the mortality benefits of moderate and high fitness persisted across three different BMI strata ( $< 20$

$\text{kg}/\text{m}^2$ ,  $20\text{--}25 \text{ kg}/\text{m}^2$ ,  $\geq 25 \text{ kg}/\text{m}^2$ ). Men and women in the moderate and high fitness groups had lower death rates than did the low fit individuals in each BMI strata. High fit men with a BMI  $\geq 25 \text{ kg}/\text{m}^2$  had an age-adjusted death rate from all causes of 20 per 10,000 man-years of observation compared to a rate of 48 per 10,000 man-years in unfit men in the same BMI group.

In 1995, we reported on observations from 9777 men from the ACLS who received two preventive medical examinations that included maximal treadmill exercise testing (46). The purpose of the investigation was to evaluate the relationship between changes in cardiorespiratory fitness and risk of mortality in men. The average length of follow-up was 5.1 years, and the main outcomes were all-cause and CVD mortality. The highest all-cause mortality rate was observed in men who were unfit at both examinations and the lowest rate was in men who remained fit at both examinations. Men who moved from unfit at baseline to fit at follow-up had an age-adjusted death rate that was 44% lower than men who were unfit at both examinations. The reduction in all-cause mortality associated with moving from the unfit to the fit category was greater than the reduction associated with a favorable change in any of the other risk factors evaluated, including BMI, and was the only statistically significant reduction in multivariate analyses (Fig. 1). In a similar study examining the influence of changes in physical activity on all-cause mortality, Paffenbarger et al. (47) showed that physically inactive middle-aged men who began to participate in moderately vigorous sports activity during the 11 years of follow-up had a 23% lower risk of dying when compared with men who remained sedentary.

In 1996, we published an investigation on 35,341 men and 7080 women from the ACLS cohort that showed that the relative risks of low cardiorespiratory fitness for all-cause and CVD mortality in both men and women were as strong as or stronger than those associated with cigarette smoking, high blood pressure, elevated cholesterol, elevated fasting glucose, and BMI  $\geq 27$  (36). In this study, high-fit persons with multiple risk factors, including cigarette smoking, high blood pressure, and elevated cholesterol, had lower death rates than low-fit persons who had none of these other risk factors.

## IV DOES PHYSICAL ACTIVITY INFLUENCE OBESITY-RELATED HEALTH OUTCOMES?

Evidence is accumulating that higher levels of physical activity and cardiorespiratory fitness provide protection against many of the adverse health outcomes

**Figure 1** Adjusted relative risk estimates and 95% CI for all-cause mortality for losing weight, lowering blood pressure, reducing cholesterol, stopping smoking, and improving fitness in men at risk for each of these risk factors at the first of two preventive medical examinations. Cutoff points for at-risk categories are in parentheses below each risk factor. Analyses were adjusted for age, family history of coronary heart disease, health status, baseline values, changes for all variables in the figure, and interval in years between examinations. (Adapted from Ref. 46.)

associated with overweight and obesity. The National Heart, Lung, and Blood Institute's Obesity Education Initiative convened an expert panel in 1995 to systematically review the scientific literature and determine the most appropriate treatment strategies that would constitute evidence-based clinical guidelines on overweight and obesity. The National Institutes of Health published the evidence report and clinical guidelines (NIH report) from this panel in 1998 (1). The panel followed a categorical system for rating the strength of the evidence using data from RCTs as the strongest level of evidence for evaluating treatment efficacy. The categorical rating system is outlined in Table 1. Of the 39 areas the panel determined required a thorough examination of the relevant scientific literature, six addressed the association of physical activity and cardiorespiratory fitness to health outcomes associated with overweight and obesity. These six evidence statements and corresponding evidence categories are presented in Table 2.

In 1999, the American College of Sports Medicine (ACSM) held a consensus conference to review and report on the scientific evidence on the role of physical activity in the prevention and treatment of obesity and its comorbidities. From this conference, the ACSM released a consensus statement from an independent expert panel and 23 scientific reviews (ACSM report) (48). The consensus statement and reviews provide an in-depth review of the role of physical activity in the treatment of overweight and obesity and expand on the evidence presented in the NIH report. Based on the scientific evidence, the ACSM's independent panel issued several consensus statements of which 10 relate to the influence of physical activity on health outcomes associated with overweight and obesity. The consensus statements and evidence categories are presented in Table 2.

A systematic review of the evidence statements from the NIH and ACSM reports reveals that there are seven specific health-related outcomes associated with overweight and obesity where there appears to be sufficient

**Table 1** Evidence Categories

| Evidence category | Source of evidence                                  | Definition   |
|-------------------|---|--|
| A                 | Randomized controlled trials (rich body of data)    | Evidence is from endpoints of well-designed RCTs (or trials that depart only minimally from randomization) that provide a consistent pattern of findings in the population for which the recommendation is made. Category A therefore requires substantial numbers of studies involving substantial numbers of participants.   |
| B                 | Randomized controlled trials (limited body of data) | Evidence is from endpoints of intervention studies that include only a limited number of RCTs, post-hoc, or subgroup analysis of RCTs, or meta-analysis of RCTs. In general, category B pertains when few randomized trials exist, they are small in size, and the trial results are somewhat inconsistent, or the trials were undertaken in a population that differs from the target population of the recommendation. |
| C                 | Nonrandomized trials<br>Observational studies       | Evidence is from outcomes of uncontrolled or nonrandomized trials or from observational studies.   |
| D                 | Panel consensus judgment                            | None of the evidence statements on fitness and health outcomes were placed in this category.   |

Source: Ref. 1.

evidence for a beneficial and often independent effect of cardiorespiratory fitness and physical activity. As outlined in Table 2, these areas include cardiorespiratory fitness, morbidity and mortality, CVD, insulin resistance and glucose tolerance, hypertension and blood pressure, lipids and dyslipoproteinemia, and cancer. In this section, we will review the scientific evidence on the influence of physical activity and cardiorespiratory fitness on obesity-related health outcomes in each of these seven areas.

### A Cardiorespiratory Fitness

The NIH report includes an evidence statement confirming the ability of physical activity to increase cardiorespiratory fitness in overweight and obese individuals independent of weight loss (1). Based on a review of 11 RCTs meeting acceptance criteria, the NIH panel placed the evidence in category A. All 11 studies showed that physical activity increased maximal oxygen uptake in men and women in the exercise groups by an average of 14–18%. Even in studies with modest weight loss (<2%), physical activity increased fitness by an average of 12–16%.

In a more recent RCT, Ross et al. (49) reported on the effects of diet- or exercise-induced weight loss or exercise

without weight loss on changes in cardiorespiratory fitness in 52 obese men (mean BMI 31.3 kg/m<sup>2</sup>) following a 12-week intervention. The investigators matched treatment groups for total energy deficit of ~700 kcal/d (dietary deficit in the diet-only group and increased energy expenditure in the exercise-only weight loss group). The exercise without weight loss group increased calorie intake by ~700 kcal/d to match the energy expenditure of exercise. Participants in the exercise groups performed daily exercise (brisk walking or light jogging) on a motorized treadmill, at an intensity of 77% of maximal heart rate for ~60 min. Body weight decreased by 7.5 kg (8%) in both weight loss groups and remained stable in the exercise without weight loss group. Maximum oxygen uptake (L/min) increased by 13% and 19% in the exercise weight loss group and exercise weight stable group compared to no change in the control and diet groups. The findings of Ross et al. demonstrate that exercise training significantly increases cardiorespiratory fitness in obese men with or without weight loss. Numerous studies show that exercise training improves  $\text{VO}_{2\text{max}}$  between 5% and 30%, with a minimum expected improvement of 15% when the quantity and quality of training meets recommended levels (50). Therefore, overweight and obese individuals appear to derive expected improvements in cardiores-

**Table 2** Evidence Statements for the Influence of Physical Activity and Cardiorespiratory Fitness on Obesity-Related Health Outcomes

| NIH evidence statements  | Evidence category | ACSM consensus statements   | Evidence category |
|--|-------------------|---|-------------------|
| 1. Cardiorespiratory fitness   |                   |   |                   |
| Physical activity in overweight and obese adults increases cardiorespiratory fitness independent of weight loss.   | A                 | Evidence not reviewed.  |                   |
| 2. Morbidity and mortality   |                   |   |                   |
| Evidence statement not given.  |                   | Higher levels of physical activity or cardiovascular fitness reduce morbidity and mortality in overweight or obese persons.   | C                 |
|  |                   | Overweight and obese persons who are physically active have a lower risk of morbidity and mortality than normal weight individuals who are sedentary.   | C                 |
| 3. Cardiovascular disease  |                   |   |                   |
| Physical activity independently reduces CVD risk factors.  | A                 | Evidence statement not given.   |                   |
| Physical activity independently reduces risk for cardiovascular disease.   | C                 |   |                   |
| 4. Insulin resistance and glucose tolerance  |                   |   |                   |
| Increased aerobic activity to increase cardiorespiratory fitness improves glucose tolerance in overweight individuals, but no evidence shows this relationship to be independent of weight loss. | C                 | Intervention-based RCTs consistently show that increased physical activity improves insulin action, and thus reduces insulin resistance, in obese subjects.   | A                 |
|  |                   | Epidemiological data suggest that exercise alone and exercise combined with weight reduction retard the transition from impaired glucose tolerance to type II diabetes.   | C                 |
| 5. Hypertension and blood pressure   |                   |   |                   |
| Increased aerobic activity to increase cardiorespiratory fitness reduces blood pressure independent of weight loss.  | A                 | RCTs provide strong evidence that physical activity can reduce blood pressure in obese subjects and that the reduction is independent of weight loss or changes in body composition. The response does not go beyond the blood pressure reduction obtained by diet alone. | A                 |
|  |                   | Observational studies support the concept that physical activity reduces the risk for developing hypertension, independent of its effects on body size or body composition.   | C                 |
| 6. Lipids and dyslipoproteinemias  |                   |   |                   |
| Increased aerobic activity to increase cardiorespiratory fitness favorably affects blood lipids, particularly if accompanied by weight loss.   | A                 | Physical activity of a volume that results in at least 4.5 kg weight loss will raise HDL-cholesterol and lower triglycerides in men and postmenopausal women.   | A                 |
|  |                   | The addition of physical activity to a low-energy, low-fat diet will reverse the HDL-lowering effect of the low-fat diet in overweight men and women.   | A                 |
|  |                   | In men and postmenopausal women with atherogenic dyslipidemia, the addition of physical activity to a modestly reducing, low-fat diet significantly enhances the LDL-lowering effect of the diet.   | A                 |
| 7. Cancer  |                   |   |                   |
| Evidence not reviewed.   |                   | Epidemiological studies find a strong inverse relationship between physical activity and colon cancer. The strength and consistency of this association is so strong that a causal connection seems likely.   | C                 |

piratory fitness from physical training with or without weight loss.

Data from the ACLS cohort indicate that overweight and obese individuals are more likely than normal-weight persons to be sedentary and unfit (51,52). There is a strong direct association between BMI and low cardiorespiratory fitness in the ACLS cohort (Fig. 2). In this cohort, ~80% of women and >90% of men with a BMI  $\geq 40$  kg/m<sup>2</sup> are unfit compared to <10% unfit in individuals with a BMI between 18.5 and 24.9 kg/m<sup>2</sup>. However, as can be seen from Figure 2, many obese individuals (BMI  $\geq 30$  kg/m<sup>2</sup>) are at least moderately fit and, as will be discussed, are likely at a lower risk for many adverse health outcomes than are normal-weight, overweight, and obese individuals who are unfit.

The importance of low cardiorespiratory fitness as a mortality predictor in obese men was demonstrated by a study reported by Wei et al. in 1999 (53). We conducted this study in 25,714 men from the ACLS cohort to compare low cardiorespiratory fitness with established CVD risk factors (type 2 diabetes, high total cholesterol, hypertension, current smoking) as a predictor of mortality in normal-weight, overweight, and obese men. In this study, baseline CVD was the strongest predictor of premature mortality. However, for overweight and obese men, low cardiorespiratory fitness was a strong predictor of mortality, with relative risks comparable with, if not greater than, those for type 2 diabetes, high cholesterol levels, hypertension, and current cigarette smoking (Fig. 3). In the 3293 obese men (BMI  $\geq 30$  kg/m<sup>2</sup>), low fitness was the most common mortality predictor with a prevalence rate about five times higher than that of type 2 diabetes, which was the least prev-

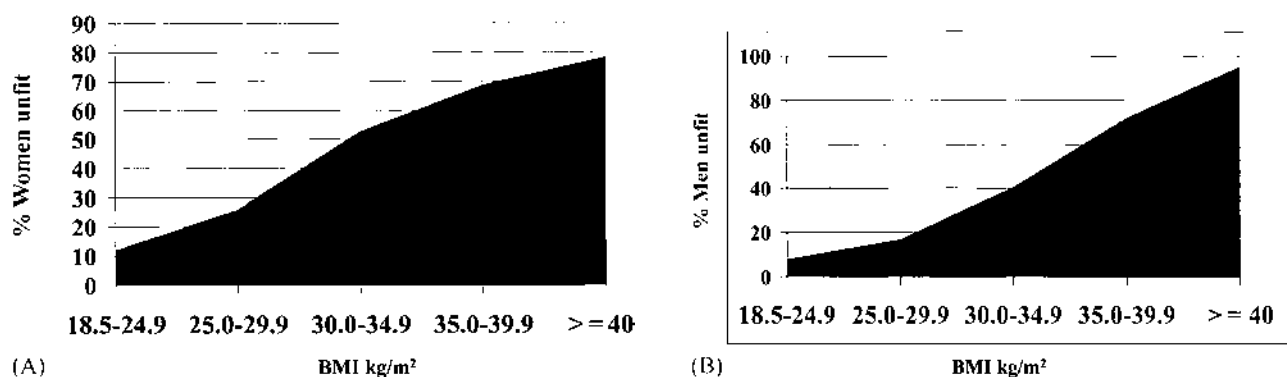

alent of the factors evaluated. About 50% of obese men in this study were unfit; 16% had baseline CVD, and 10% had type 2 diabetes. Because of its high prevalence and strength as predictor of premature mortality, low cardiorespiratory fitness had the highest population-attributable risk of the six mortality predictors evaluated in overweight and obese men in this cohort.

## B Morbidity and Mortality

The ACSM report issued two evidence statements indicating that (1) higher levels of physical activity or cardiovascular fitness reduce morbidity and mortality in overweight or obese persons, and (2) overweight and obese individuals who are physically active have a lower risk of morbidity and mortality than normal weight individuals who are sedentary (Table 2) (15). The evidence supporting these two statements was judged by the panel to be moderately strong and placed in evidence category C. In this section, we will address the available evidence on the relation of physical activity and cardiorespiratory fitness to all-cause and CVD mortality, CHD risk, and cancer in overweight and obese individuals.

### 1 All-Cause Mortality

Several prospective observational studies indicate that overweight and obese men who are fit or physically active have lower death rates than unfit or sedentary normal-weight men (54). In some of these studies, overweight and obese men only had elevated mortality if they were unfit or inactive. Unfortunately, only a few studies have included women in their analyses.

**Figure 2** The association between BMI and the prevalence of low cardiorespiratory fitness (dark area of the figure) in 6840 women (panel A) and 23,190 men (panel B) from the Aerobics Center Longitudinal Study cohort who were free of CHD, cancer, and abnormal ECG. The number of individuals across the BMI strata of 18.5–24.9, 25.0–29.9, 30.0–34.9, 35.0–39.9, and  $\geq 40$  were 5499, 959, 262, 83, and 37 for women, and 9838, 10,544, 2308, 361, and 139 for men.

**Figure 3** Relative risks for all-cause (panel A) and cardiovascular disease (CVD) (panel B) mortality by BMI and other CVD risk factors in 25,714 men followed for 258,781 man-years of observation (1025 deaths, 439 from CVD). Relative risks were adjusted for age and examination year. The referent group in each of the five analyses was normal-weight men (BMI 18.5–24.9) who did not have the CVD risk factor examined in the specific analysis. Overweight men were those with a BMI of 25.0–29.9, and obese men were those with BMI  $\geq 30.0$ . (Adapted from Ref. 53.)

In 1995, Barlow et al. (55) investigated the relation of cardiorespiratory fitness to mortality in 25,389 men classified as normal-weight, overweight, or obese ( $<27 \text{ kg/m}^2$ ,  $27\text{--}30 \text{ kg/m}^2$ ,  $>30 \text{ kg/m}^2$ ) from the ACLS cohort (55). In all three BMI categories, moderate and high-fit men had a lower relative risk for all-cause mortality than unfit men. In this report, it was also observed that moderate to high-fit men who were overweight or obese

(BMI  $\geq 27 \text{ kg/m}^2$ ) did not have elevated death rates as compared with high fit men who were normal weight (BMI  $<27 \text{ kg/m}^2$ ). The high-fit obese men also had lower death rates than low-fit men who were normal weight. Specifically, obese men (BMI  $>30 \text{ kg/m}^2$ ) who were at least moderately fit had an age-adjusted all-cause death rate of 18/10,000 man-years of observation compared with a rate of 52/10,000 man-years in normal-

weight men who were unfit. The highest death rate was observed in the unfit obese men (62.1/10,000 man-years of observation).

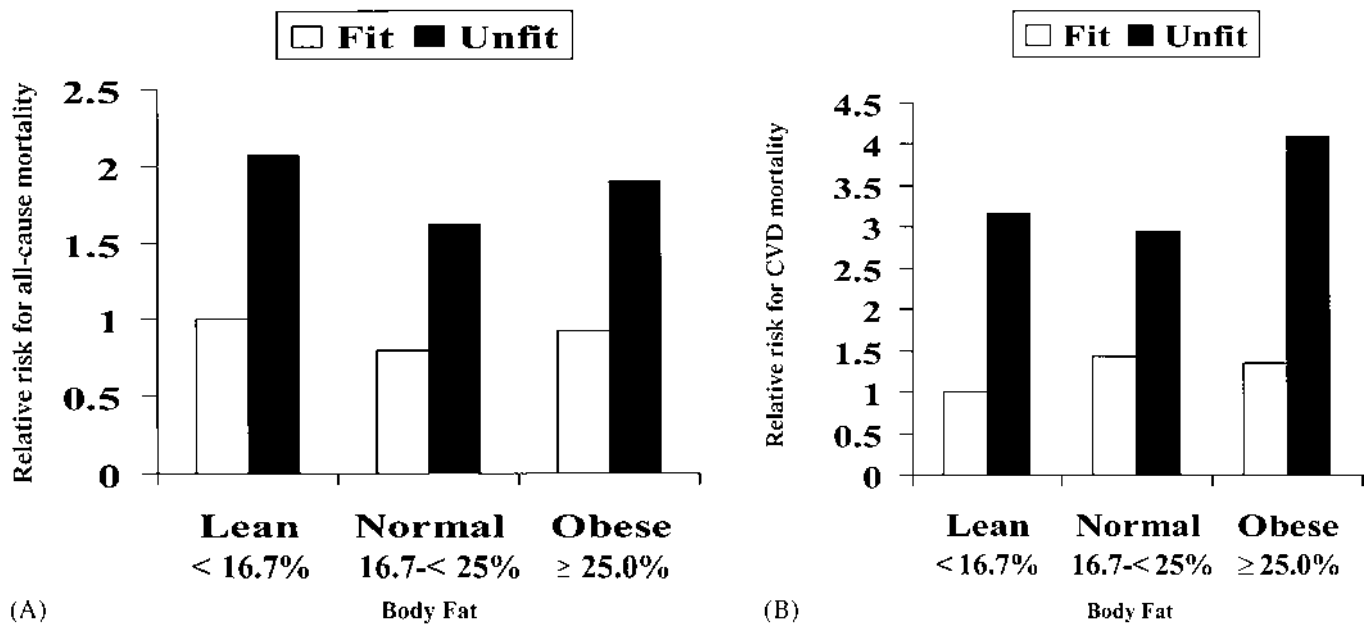

Extending the observations of Barlow and colleagues, Lee et al. (56) performed a more detailed analysis on the relation of cardiorespiratory fitness to mortality in overweight men in 21,856 men from the ACLS cohort. In this study, men with previous myocardial infarction, stroke, and cancer at baseline were excluded, and the analyses were adjusted for smoking habit and alcohol intake. The men were stratified by BMI and cardiorespiratory fitness. Normal-weight men were classified as a BMI from 19.0 to <25, mild-overweight from 25.0 to <27.8, and overweight  $\geq 27.8$  kg/m<sup>2</sup>. The investigators used two categories for cardiorespiratory fitness: (1) unfit (bottom 20th centile based on age and treadmill time) and (2) fit (the remaining 80%). Fit normal-weight men were used as the reference group in the analysis. Unfit men had a higher risk of all-cause mortality than their fit counterparts in all three BMI categories. In this study, men who were unfit and overweight had the highest risk for all-cause mortality at follow-up. However, fit and overweight

men were not at increased risk when compared with fit normal-weight men and had a lower risk for all-cause mortality at follow-up than the normal-weight but unfit men (Fig. 4A).

Lee et al. (57) extended these observations in 1999 by performing a more detailed investigation of body habitus, cardiorespiratory fitness, and mortality in 21,925 men. The investigators assigned subjects to categories of lean, normal, or obese based on measures of percent body fat (either sum of seven skinfolds or underwater weighing) and waist circumference. The results demonstrated a direct relationship between percent body fat and waist circumference measures and risk of all-cause mortality. Fit men had lower death rates than did their unfit counterparts within each body fatness and waist circumference category. Obese men, classified by either body fatness ( $\geq 25\%$ ) or waist circumference ( $\geq 99$  cm), who were fit had a twofold lower risk of all-cause mortality than unfit lean men (body fat <16.7% or waist circumference <87 cm) (Fig. 5A). All-cause mortality rates in the fit obese men were not significantly different from those of fit lean men. In summary, all three of these studies from the ACLS cohort found that overweight

**Figure 4** Body mass index and relative risks of all-cause (panel A) and cardiovascular disease (CVD) (panel B) mortality by cardiorespiratory fitness level in 21,856 men from the Aerobics Center Longitudinal Study cohort followed for 176,189 years of observation (427 deaths: 144 CVD, 143 cancer, 140 other). Adjusted for age, examination year, smoking habit, and alcohol intake. Unfit men (black bars) were the least fit 20% in each age group, and all other men were classified as fit. (Adapted from Ref. 56.)

**Figure 5** Relative risks for all-cause (panel A) and cardiovascular disease (CVD) (panel B) mortality by percent body fat and cardiorespiratory fitness level in 21,925 men followed for 176,742 man-years of observation (428 deaths: 144 CVD, 143 cancer, 141 other). Relative risks are adjusted for age, examination year, smoking status, alcohol intake, and parental history of coronary heart disease. Unfit men (black bars) were the least fit 20% in each age group, and all other men were classified as fit. (Adapted from Ref. 57.)

and obese men had elevated mortality only if they were also unfit.

A few prospective investigations provide analyses evaluating all-cause mortality as the outcome and physical activity and BMI as the exposure variables. Most of these studies provide evidence indicating that overweight and obese individuals who are physically active have a lower risk of all-cause mortality than normal weight individuals who are sedentary (32,37,54,58,59). In a study investigating the influence of leisure-time physical activity on mortality in 16,936 male Harvard alumni aged 35–74, Paffenbarger et al. (32) performed an analysis to determine the confounding influence of BMI on the inverse association between physical activity and mortality. The investigators reported on the influence of self-reported physical activity (<500, 500–1999, ≥2000 kcal/wk) across categories of BMI (<23.9, 23.9–25.2, ≥25.3 kg/m<sup>2</sup>) on all-cause mortality. In this study, BMI was not significantly related to mortality and the relation of BMI to mortality was uneven with men in the lowest and highest BMI groups having the highest death rates. When stratified by both physical activity and BMI, the results indicate lower mortality rates in active men compared to sedentary men in each

BMI group. The most active men in the highest BMI group had a lower death rate (60/10,000 man-years) than sedentary men in the two lower BMI categories (81 and 113/10,000 man-years). Rosengren and Wilhelmsen (37) also reported on an analysis investigating whether the reduction in mortality risk by physical activity varied according to baseline BMI. As for the results reported by Paffenbarger et al. (32), death rates were lower with increasing levels of self-report physical activity across all BMI categories. In this study, age-adjusted all-cause mortality rates were lower in active men with a BMI >26.6 kg/m<sup>2</sup> as compared with sedentary men with a BMI <24.1 kg/m<sup>2</sup>.

More recently, Dorn et al. (58) reported that physical activity was inversely related to all-cause mortality in nonobese men (27.02 kg/m<sup>2</sup>) but not for obese men (BMI ≥27.02 kg/m<sup>2</sup>) (58). From their results, the investigators speculated that the benefits of activity on mortality may not override the harmful effects of excess weight in obese men. In this cohort from the Buffalo Health Study, no significant interaction was observed between activity and BMI on mortality in women. Haapaaenen-Niemi et al. (59) investigated the interaction of BMI, leisure-time physical activity, and per-

ceived physical fitness with the risk of all-cause mortality (59). The study population was 2212 middle-aged and elderly Finnish men and women followed for 16 years. In this study, low levels of leisure-time physical activity (LTPA) seemed to predict and low perceived physical fitness predicted an increased risk of all-cause mortality among both men and women. However, in contrast to the hypothesis, obesity was not an independent predictor of mortality in this population, and no interaction effect was found between BMI and LTPA or perceived fitness and the relative risk of death. The authors concluded that the beneficial effects of LTPA and fitness are similar among obese and non-obese men and women.

## 2 Cardiovascular disease

Cardiovascular disease is the leading cause of death in the United States and many industrialized countries. In the United States, CVD is responsible for nearly 950,000 deaths each year (60). Both obesity and a sedentary lifestyle are strong independent predictors of fatal and nonfatal CVD (1,8). While the ACSM report does not make a specific evidence statement on CVD mortality, the review by Blair and Brodney (54) provides a summary of three prospective observational studies from the ACLS cohort that support a reduced risk of CVD mortality in fit overweight and obese men (54). In the two studies by Lee et al. (56,57), described earlier for all-cause mortality, CVD mortality was lower in fit obese men when compared with unfit lean and unfit normal weight men. In these analyses there was a tendency for fit overweight and fit obese men to have higher CVD mortality than fit normal-weight men (Figs. 4B, 5B). This finding is in contrast to the finding of no increased risk between fit normal-weight men and fit obese men for the outcome of all-cause mortality in these two studies. The NIH report contains a specific statement on the independent effect of physical activity in reducing risk for CVD morbidity and mortality, but provides no specific review of scientific literature that examines the evidence supporting reduced CVD mortality in overweight or obese individuals (Table 2).

In a more recent study examining the relation between physical activity and CVD in 1564 female alumnae from the University of Pennsylvania, Sesso et al. (61) found an inverse association for CVD risk only for lean women with a BMI  $<23 \text{ kg/m}^2$ . After multivariate adjustment, lean women who expended  $\geq 1000 \text{ kcal/wk}$  had a 37% lower CVD risk than women who expended  $<500 \text{ kcal/wk}$ . In the study from Haapanen-Niemi et al. (59), as discussed for all-cause mortality,

BMI did not appear to be an independent risk factor for CVD mortality. More studies are needed to evaluate the protective influence of physical activity on CVD mortality in overweight and obesity.

## 3 Coronary Heart Disease

Both obesity and physical inactivity are major independent predictors for CHD (1,8,25). In the United States, CHD is responsible for  $>450,000$  deaths each year and is the single leading killer of men and women (60). Neither of the evidence reports makes a specific statement on CHD; however, the review by Blair and Brodney (54) provides a summary of seven prospective observational studies that included the exposure variables of body habitus and physical activity as predictors of fatal and nonfatal CHD. In general, these studies demonstrate a protective effect of physical activity against CHD in men regardless of BMI. In a study from Salonen et al. (62), overweight men (BMI  $\geq 27 \text{ kg/m}^2$ ) who were active at work and in their leisure time had a CHD death rate of 7.4/1000 men compared with a rate of 25.9/1000 in sedentary men with a BMI  $<27 \text{ kg/m}^2$ . Morris et al. (63) reported a heart attack rate of 7.3/1000 man-years in sedentary overweight (BMI  $\geq 27 \text{ kg/m}^2$ ) men and only 1.3/1000 man-years in the most active men in the same BMI category. The rate in sedentary normal-weight (BMI  $<24 \text{ kg/m}^2$ ) men was 5.5/1000 man-years and 1.9/1000 man-years in regular vigorous exercisers. The lower rate of CHD events in these two studies suggests that physically active overweight men may have lower CHD mortality compared with normal-weight but inactive men.

Unfortunately, none of the studies reviewed by Blair and Brodney (54) were designed to specifically investigate the influence of physical activity on CHD in overweight and obese individuals. Typically, the highest BMI stratum in these studies had a lower bound in the mild-overweight category, so we cannot be certain that the results apply to obese individuals. Only one study included data for women. There are no studies examining CHD as the outcome variable and BMI and cardiorespiratory fitness as exposure variables.

Two more recent studies evaluated the relation of physical activity to CHD mortality in both men and women. In the study by Dorn et al. (58), physical activity was only associated with a decreased risk of CHD mortality in nonobese men. In the study by Haapanen-Niemi and colleagues (59), BMI was not associated with increased risk of CHD mortality in men or women; therefore, no interaction effect was found between physical activity or perceived fitness and BMI for CHD

mortality. At this time, some evidence suggests that fatal and nonfatal CHD events are lower in physically active overweight men than in either normal-weight and overweight men who are inactive; however, more evidence is needed to support an evidence-based statement on this question.

#### 4 Cancer

Cancer is the second leading killer of Americans and is responsible for >550,000 deaths each year in the United States (64). Observational studies have found a positive relation between overweight and obesity and the risk for morbidity from several types of cancer, including colon, breast, endometrial, and prostate (1,21, 27,65–67). Cross-sectional and observational studies have also found an inverse relationship between physical activity and total and site-specific cancer; however, the findings are not always consistent (33,38). Etiologic mechanisms for an interaction effect of physical activity and obesity on cancer incidence seem plausible for hormone-dependent cancers; however, the strongest evidence for a protective effect is for colon cancer (38). The most commonly cited mechanism for this effect is reduced bowel transit time, which reduces the period of contact between carcinogens and mucosal cells (38,68, 69). Two recent evidence-based reviews of physical activity and cancer risk concluded that the majority of studies observe a 10% to 70% reduction in the incidence of colon cancer, with the observed relationship being strongest for cancers of the distal colon (38,68).

Several studies also suggest that there is a dose-response association between higher levels of physical activity and decreased risk for colon cancer (33,38). While the NIH report does not make an evidence statement for physical activity and cancer risk in overweight and obese individuals, the ACSM expert panel states that current epidemiological evidence finds a strong inverse relationship between physical activity and colon cancer and that a causal connection seems likely (Table 2) (15). Although the effect of BMI has been taken into account in many studies, few studies have stratified results using both physical activity and body habitus as exposure variables (54). In a case-control study, Slattery et al. (70) stratified the incidence of colon cancer by physical activity patterns and BMI. The results suggest a protective effect of intermediate and high levels of physical activity across BMI categories, particularly in women. Given the significant limitations of current physical activity and colon cancer research, it is difficult to make any statements on the strength of evidence supporting a protective effect of physical activity independent of body habitus.

While evidence is building for a protective effect of physical activity on the risk of developing breast cancer in pre- and postmenopausal women, evidence-based statements cannot be made based on existing data (15, 33,38,68). Because of the complex relationship between body weight and breast cancer risk across the life span and the methodological limitations of current studies, it is not clear to what extent physical activity and body weight might interact to influence risk (68). Also, there are insufficient data to make evidence-based statements on the protective effects of physical activity for other obesity-related cancers such as endometrial and prostate cancers (15,33).

#### C Comorbidities

Obesity and physical inactivity are directly related to several chronic disease risk factors, such as insulin resistance, hypertension, and dyslipidemia (1,8). In this section, we review the evidence indicating a protective and often independent effect of physical activity on these disease risk factors in overweight and obese individuals.

##### 1 Insulin Resistance and Glucose Tolerance

Type 2 diabetes mellitus is a leading cause of death and disability in many countries (71). In the United States, it is estimated that nearly 15 million individuals have type 2 diabetes, and the prevalence is rising rapidly (4,72,73). Type 2 diabetes is characterized by varying degrees of insulin resistance, relative insulin deficiency, and glucose intolerance. Along with genetic factors, obesity and physical inactivity are strongly implicated in the development of type 2 diabetes (73,74). Both the NIH and ACSM reports make evidence statements about the effects of physical activity and moderate to high cardiorespiratory fitness on insulin action, glucose tolerance, and diabetes risk in overweight and obese individuals (Table 2).

Studies indicate that a single session of acute exercise at an intensity of 55–75% of  $\text{VO}_{2\text{max}}$  and a duration of 45–60 min lowers blood glucose  $20\text{--}40\text{ mg}\cdot\text{dL}^{-1}$  ( $1\text{--}2\text{ mmol}\cdot\text{dL}^{-1}$ ) and reduces insulin resistance for 2–3 days following exercise in subjects with type 2 diabetes mellitus (33,75). Studies show this effect in both obese and nonobese men and women (75). Studies examining the effects of strength training on insulin action have found similar improvements in insulin action as those induced by aerobic exercise (76). Experimental studies indicate that there are several plausible mechanisms for the beneficial effects of acute and chronic physical activity intervention on glucose homeostasis and insulin action. These mechanisms may include reduced hepatic

glucose production, increased skeletal muscle insulin sensitivity and glycogen repletion, enhanced glucose uptake, reductions in visceral and abdominal subcutaneous adipose tissue, and depletion of muscle triglycerides (76–79).

For the ACSM consensus conference, Blair and Brodney (54) evaluated prospective observational studies that stratified diabetes risk by both body habitus and cardiorespiratory fitness or physical activity. In these studies the trend was for physically active overweight and obese individuals to have a lower incidence of self-reported type 2 diabetes at follow-up compared with inactive men in the same BMI group; however, the overweight or obese men appeared to remain at higher risk when compared with sedentary normal-weight men. The most convincing evidence of a protective effect comes from a study by Wei et al. (39) in the ACLS cohort. To determine whether cardiorespiratory fitness is associated with risk for developing impaired fasting glucose and diabetes, the investigators followed 8633 nondiabetic men who were examined at least twice and followed for an average of 6 years. The strengths of this study lie in its objective measure of cardiorespiratory fitness and the determination of diabetes incidence by measured fasting plasma glucose at baseline and follow-up. In this study, after adjusting for multiple influencing factors, the investigators reported a 1.9-fold risk (95% CI, 1.5–2.4) for impaired fasting glucose and a 3.7-fold risk (95% CI, 2.4–5.8) for developing type 2 diabetes in men with low cardiorespiratory fitness (the least fit 20% of the cohort) as compared with high-fit men (the most fit 40% of the cohort). The data from this study also demonstrated a steep inverse gradient of risk for developing type 2 diabetes across fitness categories among individuals with BMI of  $<27$  and  $\geq 27$  kg/m<sup>2</sup> (Fig. 6). Fit men with a BMI  $\geq 27$  kg/m<sup>2</sup> had a slightly lower incidence of type 2 diabetes than unfit men with BMI  $<27$  kg/m<sup>2</sup>.

To date, only one RCT has been conducted that examines the influence of increased physical activity on the prevention of type 2 diabetes. The Da Qing study, conducted on 577 Chinese subjects with impaired fasting glucose, found that exercise alone, after adjustment for baseline BMI and fasting glucose, decreased the risk for developing diabetes by 46% (80). This rate of risk reduction was similar to that seen for the diet-only and diet-plus-exercise arms of the study, and the decrease in incidence was similar when individuals were stratified by BMI  $<25$  or  $\geq 25$  kg/m<sup>2</sup>.

In the ACSM Report, Kelley and Goodpaster (76) reviewed 11 randomized and nonrandomized trials that investigated the effect of aerobic exercise at recommended levels of intensity, duration, and frequency on

**Figure 6** Incidence of type 2 diabetes per 1000 person-years by cardiorespiratory fitness levels according to BMI. Of 8633 nondiabetic men at baseline examination, 149 developed type 2 diabetes during an average follow-up of 6 years. White bars indicate low-fit men (least fit 20%), diagonal lines moderate-fit men (next 40%), and black bars high-fit men (remaining 40%). (Adapted from Ref. 39.)

insulin sensitivity and glucose tolerance in relation to obesity (76). Nine of the trials reviewed indicated that physical activity resulted in improved indices of glucose homeostasis, notably improved insulin resistance, in the absence of weight loss or changes in body composition. Although physical activity appears to have an independent beneficial effect on insulin action and glucose tolerance, data from several studies suggest that greater effects occur in the presence of weight loss or a change in body composition, particularly a reduction in abdominal or visceral fat (76,78,81,82). Dengel et al. (83) reported on a 9-month intervention in 97 men assigned to one of four groups: weight loss, aerobic exercise, exercise plus weight loss, and control. The three intervention groups had significant reductions in glucose and insulin responses to an oral glucose tolerance test (OGTT) compared with the control group; however, the reduction in the insulin response for the exercise plus weight loss group was significantly greater than the other groups. A recent RCT in 52 obese men by Ross and colleagues (49) suggests the importance of weight loss in glucose control. The study found that diet-induced and exercise-induced weight loss groups matched for total energy deficit achieved similar increases in glucose disposal rates compared to the control and exercise without weight loss groups over 12 weeks of intervention. In contrast, Rice et al. (79) reported that obese men randomized to diet plus aerobic exercise or diet plus resistance exercise achieved greater reductions in the insulin area under the curve during an OGTT when compared with men in a diet only group after 16 weeks of intervention. In this study, reductions in weight and visceral and subcutaneous adipose tissue

were not different among the three treatments. In summary, while clinical trial data provide evidence that physical activity independently improves insulin action and glucose tolerance independent of weight loss, the combination of exercise plus dietary intervention to induce weight loss appears to produce more favorable changes in glucose homeostasis.

A recent study from the ACLS cohort suggests that physical activity and cardiorespiratory fitness may provide protection against premature mortality in men with type 2 diabetes. In this study, Wei et al. (84) reported on 1263 men with type 2 diabetes followed prospectively for all-cause mortality. During an average follow-up of 12 years there were 180 deaths. After adjusting for multiple influencing factors, men in the low-fitness group (bottom 20th centile based on age and treadmill time) had a risk for all-cause mortality of 2.1 (95% CI, 1.5–2.9) compared with fit men (remaining 80%). Men who reported being physically inactive at baseline had an adjusted risk for mortality of 1.7 (95% CI, 1.2–2.3) compared with physically active men. In this study, fitness had the same protective effect in normal-weight (BMI <25 kg/m<sup>2</sup>) and overweight men (BMI ≥25 kg/m<sup>2</sup>). Hu et al. (85) reported on the influence of physical activity on CVD in 5125 female nurses with type 2 diabetes over 14 years of follow-up. In this study, greater leisure-time physical activity was associated with a reduced risk of CHD and stroke, and the inverse association persisted in a subgroup analysis stratified by BMI. The results of these two studies suggest that physical activity and cardiorespiratory fitness have strong and independent effects on morbidity and mortality in individuals with type 2 diabetes and that the protective effect extends to both normal weight and overweight individuals.

## 2 Hypertension and Blood Pressure

Hypertension is a leading cause of CVD morbidity and mortality. In the United States it is estimated that >50 million individuals have hypertension, with many cases undiagnosed (60). The long-term complications associated with hypertension include atherosclerotic cardiovascular, cerebrovascular, and peripheral vascular disease. Weight reduction and increased physical activity are widely accepted lifestyle interventions for the management of hypertension (86). Both the NIH and ACSM expert panels conclude that physical activity reduces blood pressure independent of weight loss and place the evidence in category A (Table 2). Observational studies suggest that physical activity reduces the risk for developing hypertension independent of body

habitus (15,54,87). Paffenbarger et al. (88,89) followed two cohorts of male college alumni for up to 15 years for the development of incident physician diagnosed hypertension. In general, men participating in vigorous sports play had a lower risk of developing hypertension than sedentary men, with the greatest protection occurring in men in the highest BMI categories. Evidence from cross-sectional surveys and prospective observational studies is supported by RCTs (87). Investigators have identified several plausible mechanisms for this beneficial independent effect of physical activity on blood pressure. Such mechanisms may include reduced peripheral vascular resistance, decrease in plasma catecholamine concentrations, changes in autonomic regulation, and decreased plasma volume (87,90).

There is strong evidence that a single session of exercise at an intensity of 50–100% of  $\text{VO}_{2\text{max}}$  produces a lowering of 18–20 mm Hg in systolic and 7–9 mm Hg in diastolic blood pressure with the maximal changes occurring in individuals with stage I hypertension (33,75). The post exercise hypotension may persist for up to 12–16 hours after exercise, thus offering individuals with hypertension a significant amount of protection on days that activity is performed. A recent meta-analysis of 44 RCTs found that aerobic training from three to five times per week for 30–60 min per session and at an intensity of at least 40–50% of maximal exercise reduces blood pressure, particularly in hypertensives (91). In this review, Fagard determined that aerobic exercise training reduces blood pressure, after controlling for weight loss and dietary change, by an average of 3.4/2.4 mm Hg. The blood pressure reduction in response to exercise training was greater in hypertensive individuals (7.4/5.8 mm Hg). In an earlier meta-analysis and evidence-based review for the ACSM report, Fagard (87) summarized the results from 64 study groups according to whether the average baseline BMI was <25 or ≥25 kg/m<sup>2</sup>. Reductions in blood pressure associated with exercise training were similar in the two BMI groups, although BMI decreased significantly in the overweight but not in the lean subjects. A metaregression analysis of these data demonstrated that there were no significant relationships between changes in blood pressure associated with exercise training and initial BMI or changes in BMI.

Several recent investigations indicate that exercise training alone, while effective, is less effective for reducing blood pressure than diet-induced weight loss in overweight and obese individuals (82,87). In his review, Fagard also compared exercise training versus dietary intervention in 11 study groups (87). The reduction in blood pressure and BMI with diet alone was signifi-

cantly greater than that of exercise alone. It is likely that the greater reduction in blood pressure seen with the dietary interventions is due to weight loss. Some studies indicate that exercise-induced and diet-induced weight losses appear to produce similar reductions in blood pressure (92,93). In addition, several studies indicate that there is not a synergistic effect on blood pressure control when exercise is combined with dietary therapy (83,87,92). Fagard compared diet alone with combined diet and exercise in 11 study groups and found that there was not an additive blood pressure lowering effect for the combined intervention, although the combined intervention was more effective in reducing BMI (87). However, a more recent study, by Blumenthal et al. (94), found that the addition of a behavioral weight loss program enhanced the blood pressure lowering effect of exercise alone. It is important to note that in several of these studies exercise training significantly increased fitness compared with no change with diet-induced weight loss (1,8,83,92). Work from our center provides evidence that moderate to high levels of fitness may provide an independent protective effect against premature mortality in normotensive and hypertensive men (95).

### 3 Lipids and Dyslipoproteinemias

It is widely accepted that blood lipids are a major factor in the process that leads to atherosclerotic CVD (96). Treatment of unfavorable lipid levels reduces the incidence of fatal and nonfatal CHD events (97). A large body of evidence from cross-sectional observational studies, clinical trials, and experimental investigations supports a beneficial effect of physical activity on blood lipids, particularly HDL cholesterol (HDL-C) and triglycerides (15,33,98,99). The most frequently observed change associated with physical activity intervention is an increase in HDL-C. Exercise training also appears to attenuate the reduction in HDL-C accompanying decreased dietary intake of saturated fat and cholesterol. Less frequently observed are decreases in total cholesterol and LDL-C. According to Leon and Sanchez, exercise training in RCTs typically involved moderate to vigorous exercise three to five times per week for 30–60 min and a study duration of 12–52 weeks (98). There is also strong evidence for an acute beneficial effect of endurance exercise on HDL-C and triglycerides (33,75). Experimental investigations have identified several possible mechanisms for the favorable influence of physical activity on lipid levels. The mechanisms include increases in lipoprotein lipase activity, decreases in hepatic triglyceride lipase activity, and depletion of intramuscular triglycerides (75).

Both the NIH and ACSM reports place evidence for a favorable effect of physical activity on blood lipids in overweight and obese individuals in category A, particularly if the physical activity is accompanied by weight loss (Table 2). Although the body of evidence is small, it appears that much, if not most, of the effect of physical activity on lipid levels in overweight and obese individuals is mediated through changes in weight and body composition. The ACSM consensus panel determined that physical activity of a volume that results in at least a 4.5-kg weight loss will raise HDL-C and lower triglycerides in men and postmenopausal women (15). The addition of physical activity to caloric deficit low-fat diet may reverse the HDL-C lowering effect associated with this eating pattern in overweight men and women. Physical activity significantly enhances the LDL-C-lowering effect of a weight-reducing low-fat diet (15,99). However, it is important to note that the number of studies evaluating the effects of physical activity in overweight or obese individuals with adverse lipoprotein profiles is very limited.

In the ACSM report, Stefanick (99) provides an evidence-based review of RCTs on the effects of physical activity on dyslipoproteinemias in overweight and obese men and women (99). Stefanick reviewed six RCTs conducted in men and/or women with a mean BMI of 25 to 29.9 kg/m<sup>2</sup> and five studies in obese men or postmenopausal women (BMI ≥ 30 kg/m<sup>2</sup>). In a trial of 132 overweight premenopausal women, diet plus exercise significantly increased HDL-C compared to diet only intervention, but not compared to controls (100). There were no significant differences in total cholesterol, LDL-C, or triglycerides between the intervention groups. The diet only group had a nonsignificant decrease in HDL-C, which indicates that the exercise may have offset the HDL-C-lowering effect of the hypocaloric, low-fat diet. In the five other studies reviewed involving overweight men and women, there were no significant changes in total cholesterol, triglycerides, or HDL-C levels when exercise only groups were compared to controls or when diet plus exercise was compared to diet alone. However, in three trials, the addition of aerobic exercise to diet resulted in significant improvements in lipids compared with controls. In one study, men and women who adopted a National Cholesterol Education Program Step 2 Diet and aerobic exercise significantly reduced LDL-C compared to controls (101). In her review, Stefanick concluded that the addition of exercise to a weight-reducing diet and/or reduced-fat diet in overweight men and women produced only modest benefits in HDL-C, triglycerides, and LDL-C compared to that achieved by diet alone. Of

the five studies reviewed in obese men and women, only one demonstrated a favorable effect of diet plus exercise compared to diet alone on HDL-C and triglycerides (100).

## V RECOMMENDATIONS

### A Research

The current body of evidence evaluating the association of physical activity to obesity-related health outcomes is limited. As reviewed, few studies have specifically evaluated the independent influence of physical activity on obesity-related health outcomes. In addition, most studies evaluating the association of overweight and obesity to morbidity and mortality fail to appropriately account for the potential confounding influence of physical activity and cardiorespiratory fitness on health outcomes. In studies where physical activity is considered, it is often measured so crudely that there is too much misclassification to have high confidence in the data. To determine and account for the independent association of physical activity to morbidity and mortality in overweight and obesity, results from prospective observational studies must be presented by both strata of body habitus and physical activity with better control for potential confounding factors such as changes in diet and health status. Unfortunately, few of the available studies in this area include women, older subjects, or minority groups. In addition, most studies are limited to overweight and class I obesity, with few individuals with higher levels of obesity. The current body of evidence is particularly limited for other obesity-related health outcomes such as cerebrovascular disease, functional disability, osteoarthritis, cancer, prothrombotic states, mood disorders, and health-related quality of life (15,33).

To improve the quality of data, researchers must develop better methods of assessing and quantifying physical activity in overweight and obese individuals. We need improved surveillance methods for monitoring physical activity patterns and trends within populations to better understand and characterize the influence of activity patterns on the increasing prevalence of overweight and obesity. More data are needed to better characterize environmental, psychosocial, and behavioral trends that influence weight, physical activity participation, and health outcomes. The major determinants of physical activity participation by overweight and obese individuals must be assessed and effective public health and clinical interventions developed to promote the adoption and maintenance of beneficial

levels of physical activity. Research efforts must be directed at finding effective ways to apply behavioral theories and methods to physical activity counseling and intervention in the clinical setting.

Investigators must employ better design for RCTs to account for the complex interrelationships and synergistic effects between physical activity, body weight, adiposity, dietary change, and health status on health outcomes. More RCTs must be conducted to better characterize the mechanisms by which physical activity influences obesity-related health outcomes and disease risk factors. More research is needed to determine the minimal and optimal levels of physical activity necessary to favorably influence disease risk factors and health outcomes in overweight and obese individuals. Variables of importance include the length of intervention and the frequency, intensity, duration, and total dose of physical activity. The objective of this line of research is to better characterize the quantitative effect or dose-response relationship of physical activity to obesity-related health outcomes.

### B Public Health

The public health burdens of physical inactivity and obesity are substantial. Recent reports indicate that obesity and the contributing lifestyle factors of physical inactivity and poor dietary habits are responsible for between 14% and 23% of total mortality in the United States (29). Overall, the total direct healthcare delivery cost associated with obesity and physical inactivity account for some 9.4%, over \$94 billion, of national health care expenditures in the United States (29). Given the disease burden and public health impact of obesity and its increasing prevalence, population-based strategies for obesity prevention deserve increasing emphasis and attention. It is likely that the prevalence of low fitness is substantially higher than the prevalence of other obesity-related disease risk factors, such as diabetes. Given the high prevalence of both physical inactivity and obesity and strong association with all-cause and CVD mortality, the population-attributable risk associated with low fitness levels in obese individuals is substantial (53). Ultimately, for obesity control at the population level, public health and environmental policies aimed at increasing opportunities for physical activity are of paramount importance.

Research and clinical experience must be used to help guide public policy decisions. Public health organizations and educational institutions must communicate to governmental agencies and the public the importance of physical activity in improving health

and preventing weight gain. Organizations and agencies must help develop and implement effective strategies to promote the adoption of physically active lifestyles among all members of society. We need to take special actions to target population subgroups where physical inactivity and obesity are particularly prevalent. Researchers and clinicians must assume a leadership role in the promotion of physical activity at the public health level. Public health efforts must be directed at strategies to create public environments that are conducive to physical activity, particularly for overweight and obese individuals.

To achieve these public health goals, several things must happen:

1. Communities need resources to develop parks, walking and bicycle paths, playgrounds, recreation centers, and safe neighborhoods.

2. Worksites and public buildings must provide facilities and programs that encourage physical activity and increase access for all individuals.

3. Architectural designs must begin to make stairs more accessible and appealing and include parking areas that encourage walking.

4. School-based programs must capitalize on the opportunity to promote physical activity among a large number of children, adolescents, and their families.

5. Media messages and public awareness campaigns to encourage active lifestyles and healthy weights need to be developed and delivered.

6. More citizens need to develop and apply behavioral skills to avoid the allure of technologies that promote sedentary living.

## C Clinical Practice

It is clear that regular physical activity is helpful for weight control and provides important health benefits for overweight and obese individuals. Because of these benefits, professional and governmental bodies have provided expert consensus documents and recommendations on physical activity both for the treatment of overweight and obesity and for health enhancement in the general population (1,8). However, despite general consensus and expert guidelines, the barriers to physical activity counseling and participation present significant challenges for clinicians and patients, respectively. A recent survey of U.S. adults found that, of 44% of women and 29% of men trying to lose weight at any given time, <40% report engaging in the recommended 150 min or more of leisure-time physical activity per week (102). Another survey found that >54% of overweight and obese patients are not receiving exercise

counseling from their physicians (103). Health care professionals face several established barriers to physical activity counseling in clinical practice including lack of time, inadequate reimbursement, and little training in physical activity and behavioral counseling. Despite the barriers, available evidence indicates that clinicians must assess physical activity and fitness status in overweight and obese individuals to allow for a more complete risk stratification and enhanced clinical decision making. We feel that it is as important for health care professionals to provide physical activity assessment, prescription, and counseling as it is to assess and treat other obesity-related comorbidities, such as diabetes and hypertension. Given the beneficial effects of physical activity on health outcomes, health care professionals have the responsibility to routinely promote physical activity to increase cardiorespiratory fitness in all patients. Clinical research must guide the development and implementation of policies and programs that will eliminate the barriers to physical activity counseling and participation and promote the application of proven physical activity interventions in clinical practice.

Available evidence favors a combination of dietary, physical activity, and behavioral intervention as the most important strategy for weight loss and maintenance in clinical practice (1). Although questions remain as to the minimal and optimal doses of physical activity needed to favorably influence obesity-related health outcomes, available evidence indicates that current public health recommendations for a minimum of 30 min of moderate-intensity physical activity accumulated on most, preferably all, days of the week will result in significant health benefits for overweight and obese individuals. Some evidence suggests that higher levels of physical activity may be needed to produce significant weight loss or promote long-term weight maintenance (104,105). Applying validated behavior modification techniques in clinical practice and educating patients on alternative approaches to physical activity, such as lifestyle physical activity and the accumulation of short bouts of moderate to vigorous activity, may improve patient participation in and adherence to clinically beneficial levels of physical activity (106–109). It is important to recognize that physical activity is a behavior that requires certain skills to integrate it into one's lifestyle. We believe far more success can be achieved if clinicians and patients focus on developing the behavioral skills (i.e., goal setting, problem solving, and self-monitoring) needed to increase physical activity and improve health rather than the traditional focus on the attributes of weight and body composition. We have

published specific guidelines and programs for using physical activity in this way (106,110,111). We also recommend that all healthcare professionals adopt a physically active lifestyle themselves. Clinicians who are active and fit will not only benefit personally, but also be better able to counsel patients on the benefits of adopting and enjoying a physically active lifestyle.

## VI CONCLUSIONS

Current evidence indicates that higher levels of physical activity and cardiorespiratory fitness have a beneficial influence on several adverse health outcomes associated with overweight and obesity. For many of these adverse health outcomes, moderate to high levels of physical activity and cardiorespiratory fitness provide benefits independent of changes in weight or body composition. Overweight and obese individuals who are or who become physically active have better risk factor profiles and lower rates of disease and death than overweight and obese individuals who are inactive and unfit. Physical activity appears to work synergistically with dietary intervention and weight loss to produce more favorable risk factor profiles in overweight and obese individuals. Although the current body of research is limited, some evidence suggests that fit overweight and obese men have lower rates of all-cause and CVD mortality when compared with normal-weight men who are unfit. More research is needed to evaluate the extent to which physical activity attenuates mortality risk in overweight and obese individuals. More public health efforts and clinical strategies for promoting physical activity are needed to decrease the incidence of obesity and its associated adverse health outcomes.

## ACKNOWLEDGMENTS

We thank Melba Morrow and Ginny Shead for editorial review and assistance with manuscript preparation. We thank Dr. Kenneth H. Cooper and the staff of the Cooper Aerobics Center for making this work possible. The work reported here is supported in part by National Institutes of Health grants AG06945 and HL48597.

### I OVERVIEW OF RESEARCH EVIDENCE

Quality of life, particularly health-related quality of life, has been defined as the “physical, psychological, and social domains of health, seen as distinct areas that are influenced by a person’s experiences, beliefs, expectations, and perceptions” (1). This definition makes it explicit that quality of life includes not only objective indicators but also subjective appraisals of well-being. Further, the growing interest in assessing quality of life reflects the recognition that health is much more than the absence of disease.

Obesity is at once a chronic condition with numerous effects on physical health and functioning, a publicly apparent characteristic with pervasive social implications, and a vexing health problem whose remediation or control requires long-term, often difficult behavioral changes. It is thus expected that obesity may affect quality of life in many ways. A growing body of research has examined the quality of life experienced by obese persons. Quality of life in obesity has been studied with questionnaires explicitly assessing a range of areas of life functioning, with assessment of specific psychiatric disorders or moods, and with examination of other indicators of life quality. We will approach this research from the point of view that different aspects of quality of life may be affected by obesity in different ways, and

that various factors influence how obese individuals are affected.

The present section describes measures of overall quality of life, mood and personality, eating behavior and disturbed eating, dietary restraint and overeating/binge eating, and body image. Sections II–IV of this chapter provide a review of research findings pertaining to obesity and quality of life. Section V describes frequently used assessment methods that measure various aspects of quality of life. When reading these sections, the reader may wish to refer to the section on methods if there are questions about the reliability and validity of a particular measure that was used to assess the relationship between obesity and quality of life.

### A Obesity and Quality of Life

#### 1 Overall Quality of Life

Two questionnaires that have been frequently used in this research are the Impact of Weight on Quality of Life questionnaire (2) and the Medical Outcomes Study Short-Form Health Survey (SF-36) (3). They are described in more detail later in this chapter. Among a sample of treatment-seeking obese men and women, functioning in most areas of the Impact of Weight on Quality of Life questionnaire was worse with increasing body mass index (BMI). Women reported greater

impact on Self-Esteem and Sexual Life than did men (2,4).

Obese persons seeking weight loss treatment have reported worse functioning in all eight domains of the SF-36, especially bodily pain and vitality, compared to population norms. Differences remained after controlling for sociodemographic factors and certain comorbidities including depression. Physical and social functioning was worse among the most severely obese in the sample. Bodily pain scores were comparable to those of migraine sufferers (5).

Again using the SF-36, Fontaine et al. (6) found more impaired functioning among a group of treatment-seeking obese people compared to a group of obese respondents not trying to lose weight. The differences were primarily on measures of physical functioning, consistent with the higher average BMI and higher prevalence of hypertension, chronic pain, and diabetes among the treatment seekers. However, differences on bodily pain, general health and vitality persisted after controlling for sociodemographic and medical variables on which the groups also differed. Further, among an obese treatment-seeking sample, worse physical functioning was related to greater BMI, higher age, report of pain, and male gender, although few such relations were seen with mental functioning scores (7).

With other measures of quality of life, baseline assessment of participants in the Swedish Obese Subjects study (BMIs  $\geq 34$  for males,  $\geq 38$  for females) revealed lower subjective ratings of current health, worse social functioning, and lower rates of employment, compared to population norms and other reference groups. Women reported worse general health than men, while the reverse was true of the measure of social functioning. Indices of somatic morbidity (joint symptoms, angina pectoris, days in hospital) and of previous psychiatric morbidity were associated with worse ratings of current health and social functioning (8).

With a mail survey of nearly 9000 adults in the Oxford region of England, Doll et al. (9) assessed the association of obesity with quality of life as measured by the SF-36. Increasing degrees of obesity were associated with decreasing physical well-being, regardless of the presence or absence of other chronic medical conditions. Emotional well-being was adversely affected only for those obese subjects with chronic medical conditions, and their emotional functioning was not significantly different from that of nonobese subjects with equal degrees of chronic illness. However, the obese subjects were significantly more likely to report having chronic illness.

Brown et al. (10) assessed the effects of obesity among a large population-based sample of Australian women 18–23 years of age, using the SF-36. They found that even among this young group, functioning was lower among overweight and obese groups on the measures of general health, physical functioning, and vitality.

Other objective indicants of quality of life reflect impaired quality of life for many obese people. Obesity in adolescence and/or early adulthood has been found at follow-up 7 years later to predict lower rates of marriage, and for women, lower educational achievement and income and higher rates of poverty in American (11) and British (12) samples. Relative to thinner women, heavier women are more likely to marry men of lower socioeconomic status (13).

Additional evidence regarding the perceived effect of obesity on quality of life may be inferred from the degree of value placed by obese people on achieving a lower weight goal. Rand and MacGregor (14) reported that gastric bypass patients who had lost at least 45 kg (100 lb) indicated that they would prefer to be blind, deaf, dyslexic, diabetic, or an amputee rather than return to their former severely obese status, and stated unanimously that they would forego the opportunity to be a millionaire if it required them to be obese again. In another study, obese treatment seekers and obese and nonobese members of a community sample answered forced-choice items assessing what they would hypothetically sacrifice or endure to reach and maintain their personal weight goal (15). Nearly 90% or more of the treatment-seeking obese, and 40% or more of the non-treatment-seeking obese, said they would be willing to forego a job promotion, retiring with full pay, eliminating the national debt, or winning their dream house or car or an all-expenses-paid vacation. Smaller majorities of the treatment seekers said they would suffer loss of half their income or a job demotion, although relatively few of the community obese sample were willing to incur negative events. Figures 1 and 2 summarize these findings. From the findings of these studies, it is apparent that obesity is a status that is loathed by those who have developed excess adiposity.

## 2 Psychological Functioning

Although obesity is not a psychiatric diagnosis (16), a lengthy literature has assessed psychological functioning among obese persons. It appears that among non-clinical samples of obese people, rates of diagnosable psychopathology are no greater than among nonobese groups (17–20). However, lifetime prevalence rates of

**Figure 1** Hypothetical positive events foregone to reach weight goal. <sup>a</sup>Treatment-seeking obese participants differ from non-treatment-seeking obese participants. <sup>b</sup>Non-treatment-seeking obese participants differ from nonobese participants ( $P < .01$ ). (From Ref. 15.)

certain psychiatric disorders in the general population are substantial; thus, any obese group may be expected to include a number of people so afflicted, independent of weight status.

Nonetheless, clinical samples of people seeking treatment for their obesity have been shown to display prevalence rates of psychiatric disorders and other measures of psychopathology higher than those seen among the general population. Among persons seeking professionally directed dietary, pharmacological, or surgical treatment, lifetime prevalence rates of 48–57% have been reported for axis I (e.g., anxiety or depression) psychiatric disorders (21–23). This compares to general population rates of 26–35% (24). One study found the lifetime rate of personality disorder diagnoses was 57% among applicants for outpatient treatment (21).

Moderately to severely obese men and women assessed at entry to the Swedish Obese Subjects study described lower mood states and more symptoms of depression and anxiety compared to a healthy reference group. Further, their overall mood scores were worse than those of samples of rheumatoid arthritis patients,

recurrence-free cancer survivors, spinal cord injury victims, and intermittent claudication patients. The obese participants' anxiety and depression scores were also higher than most of these groups (8).

It has been observed that the extent of psychological distress among obese treatment-seeking groups is similar to that observed among other groups of medical or surgical patients (19). This observation suggests that the higher rates of distress among obese subjects observed in clinical studies, compared to population-based studies, reflect a selection bias in which those who are more distressed seek treatment. Indeed, when treatment-seeking obese samples have been compared to nonclinical obese samples, higher rates of psychological disturbance or distress have often been found among the treatment-seeking patients. For example, among obese females, those seeking treatment were more depressed and histrionic than those from a nonclinical sample (25). In another study, obese people applying for weight loss treatment reported more symptoms of borderline personality disorder than groups of nonclinical obese or nonobese controls, and only the treatment-seeking obese subjects showed more psychiatric symp-

**Figure 2** Hypothetical negative events to be incurred to reach weight goal. <sup>a</sup>Treatment-seeking obese participants differ from nontreatment-seeking obese participants ( $P < .01$ ). (From Ref. 14.)

toms than the nonobese controls (17). A sample of treatment-seeking extremely obese adolescents and young adults demonstrated higher prevalence rates of mood, anxiety, somatoform and eating disorders, compared to a less obese population group and a general population group (26).

It has been contended that rather than asking whether obesity per se increases the risk of psychopathology or psychological distress, research should attempt to determine which obese people are more vulnerable to associated psychological disturbance (32). Such studies may reveal not only subgroups that are more susceptible to obesity-related psychological distress, but other subgroups that are more resilient. For example, one study of the relation of BMI to depressive symptoms among an older (50–89 years old) community sample in California found that whereas there was a trend for heavier women to have more depressive symptoms, obese men actually had lower scores on the Beck Depression Inventory than did their non-obese counterparts (27).

Although there are some reports of impaired self-esteem among adult obese patients (2) and, to a lesser degree, nonpatient obese adults (28), much research in

this area has focused on children and adolescents. Studies of the effects of obesity on self-esteem among preteenage children have yielded inconsistent results, with some finding lowered self-esteem and others finding no differences. However, the deleterious effects of obesity on self-esteem are more consistent among adolescents and young adults (29–31). While some studies have shown that in some groups (e.g., white and Hispanic females), obesity in the preteen years predicts impaired self-esteem in early adolescence (30), other studies have suggested that causality may be bidirectional. Studies of black middle-school girls and boys and of white adolescent girls found that higher self-esteem scores were associated with lower weight gain over the next 1–3 years (29).

### 3 Interpersonal Consequences of Obesity

One pervasive, consistent effect of obesity on quality of life is seen in the social realm. It has been widely noted that at least in the United States and other Western societies, obese people inhabit a world that is poised to treat them badly (19,20,32,33). Negative attitudes toward obese people have been demonstrated among

adults and children, even preschoolers (19,20,33,34). Unfortunately, they have also been found among health care professionals (35–38). Obese women in weight loss treatment reported less satisfaction with and confidence in their physicians' management of their obesity than of their general health. However, fewer than 10% reported frequent, negative interactions with their physicians concerning their weight (39).

Negative attitudes are frequently reflected in prejudicial behavior against obese people. The extent of discrimination in employment and educational settings has been frequently documented (11,33,40,41). Obese adults frequently report perceived mistreatment due to their weight at the hands of strangers and loved ones alike, with the frequency of such reports related to degree of obesity (42).

One result of repeatedly interacting with a world that is often flinty and at worst hostile may be a reduction in opportunities to develop certain social skills. For example, in a study in which obese and nonobese women conversed on the telephone with anonymous partners who were unaware of their weight status, the obese women were rated by both the partners and reviewers of the taped conversations as being less friendly, less likable, less attractive, and less socially skilled (43). However, the same research team later found no differences between obese and nonobese women in the rated quality of their actual relationships or social behavior, based on ratings by both participants and their friends and coworkers (44). Interestingly, a study of 9-year-old British schoolgirls found that although the overweight and obese girls were less likely than nonoverweight girls to be rated as pretty by peers, they were just as popular as measured by peer nomination questions (45).

## **B Is There an "Obese Personality"?**

Stereotypic views of the personality makeup of obese persons have been long and widely held by the public and by professionals. For example, in 1941 psychoanalyst Hilde Bruch (46) noted: "It is a matter of common knowledge that obese people show certain similarities of character and behavior. According to popular opinion, fat people are cheerful and easygoing. They enjoy life in general, and good, rich food in particular." Bruch (46) took issue with that lay view: "This popular concept has been challenged as incorrect for the obese adult. . . . It certainly is not true for the obese child. On the contrary, obese children are fundamentally unhappy and maladjusted. Timid and retiring, clumsy and slow, they are not capable of holding a secure place among other children."

It is noteworthy that Bruch challenged only the accuracy of the popular stereotypes, not the underlying assumption that there was a common set of personality characteristics that captured the behavioral and psychological functioning of obese adults or children. Personality traits represent psychological and/or behavioral dimensions which vary broadly across members of the normal population, but on which a particular person is generally consistent across time and situations. For example, extraversion/introversion, rigidity/flexibility, masculinity/femininity, dominance/submission, and obsessive-compulsive tendencies may all be considered personality traits. There is little consistent evidence that obese people differ from the nonobese on such general dispositional traits, and little evidence that there are significant personality characteristics that are unique to obese persons (47,48).

In contrast to personality traits, personality type can be thought of as the relative configuration of various individual traits. In order to demonstrate that there is an "obese personality," there should be evidence that the obese population has personality types that are generally homogeneous within that group and generally different from those types seen in the nonobese population. Neither type of evidence has been reported. One cluster analysis of Minnesota Multiphasic Personality Inventory profiles of 170 women applying for obesity surgery found that there were five derived cluster profiles that were similar to those found in other populations. Further, these five nonunique prototypes described barely more than half the subjects (49). It is unlikely that the broader and much more diverse population of obese persons is any more homogeneous or different from nonobese people than was this group of surgery applicants. Given the sheer numbers of the obese population, it is improbable that so many individuals could be described by a very small number of personality types.

## **C Body Image and Obesity**

The term body image has been used to describe many aspects of perceived physical appearance. Generally, body image refers to one's perception or evaluation of body size and shape (50–52). Using this definition, body image is not defined as satisfaction with other aspects of physical appearance, which might include such features as complexion, hair, facial shape, etc. Instead, body image specifically refers to the perception or evaluation of *body shape* or *size*. Body image is often defined as the estimation of body size (including actual and ideal body size) or as body size dissatisfaction. Body size

dissatisfaction is often measured using questionnaires about satisfaction with various body parts or with the whole body (53). However, body size dissatisfaction has also been defined as the discrepancy between actual and ideal body size (54), and this actual-ideal discrepancy measure is highly correlated with questionnaire measures of body size dissatisfaction (55,56).

Studies of body size dissatisfaction have found that obese people are more dissatisfied with body size than are nonobese controls, though this relationship is moderated by the *perception* of being overweight, as opposed to actually being overweight (57), as defined by conventional standards such as BMI. Generally, the severity of body size dissatisfaction is positively correlated with actual body size (56), though certain other variables, e.g., ethnicity and gender, moderate this relationship (56–58). One consistent finding is that African-American men and women report lower levels of body size dissatisfaction than white men and women (56). Concerns about body size and shape also differ as a function of gender and sexual orientation. For example, Strong, et al. (59) found that heterosexual women were most highly concerned about body size, followed by gay men and lesbians, who did not differ, and all groups had greater body size concerns than did heterosexual men.

Studies of body size estimation by obese persons have yielded variable results. Some studies have found that obese persons are more likely to overestimate body size (60–62), while other studies have failed to find this phenomenon (32,63,64). In general, as BMI increases, the discrepancy between actual and ideal body size increases dramatically (65). A recent study found that in comparison to black adults, white men and women overestimated actual body size and underestimated ideal body, resulting in greater body size dissatisfaction in overweight/obese white adults (56).

## **D Dieting and Disturbed Patterns of Eating**

Over the past 25 years, there has been a widely held belief that dieting leads to binge eating or overeating (66). This perspective led to the conclusion that dieting may be hazardous to one's health, causing weight cycling, binge eating, and other adverse health consequences (67,68). Other reviews of the literature, e.g., Yanovski (69), found few if any significant short-term or long-term effects of weight cycling. Therefore the validity of the perspective that dieting causes disturbed patterns of eating has been challenged in the past decade. A key concept for this perspective was dietary restraint. According to this view, voluntary intention

to restrict energy intake was often disrupted, causing "disinhibited eating," whereby the person overate since the prohibition against eating had been violated (70).

Over the past 25 years, a number of laboratory studies have supported this conclusion (71), but a number of studies have also questioned the validity of this theory (72–75). An important consideration when reviewing this literature is the methodology for measuring dietary restraint. For example, Stunkard and Messick (76) developed a questionnaire that separated dietary restraint and the susceptibility to overeat. Using this questionnaire, a number of studies have found that some people who are attempting to restrict energy intake can successfully do so and, as a consequence, can maintain lower body weight without adverse psychological consequences (72,74). Other studies have suggested that there may be safe (flexible) dieting strategies and unsafe (rigid) dieting strategies (73,77). Flexible dieting strategies are characterized by less rigid rules about weight management and have been found to be associated with less severe binge eating and mood disturbances. However, it should be noted that all of the studies on rigid versus flexible dieting have used cross-sectional research designs, so it is not possible to discern if the relative absence of adverse psychological correlates is a direct consequence of flexible dieting or whether lower levels of psychological disturbance may allow for the presence of less rigid weight control strategies to manage body weight.

Finally, there is some evidence that extreme obesity may be associated with unrestrained overeating (72,74). Lowe (75) has suggested unrestrained overeaters may represent people who have tried unsuccessfully to restrict energy intake in the past, and who gave up in despair, resulting in relatively rapid weight gain until extreme obesity is achieved. A National Task Force on the Prevention and Treatment of Obesity (76) concluded that dieting for weight reduction was relatively safe, with greater potential benefits than costs.

## **II RISK FACTOR MODELS OF QUALITY OF LIFE ASSOCIATED WITH OBESITY**

### **A Introduction and Basic Concepts**

Psychological research over the past 40 years has failed to find that in general, obese people have a higher level of psychological problems than do nonobese people. Instead, this research has found that obese people struggle with specific problems related to being overweight, e.g., body dissatisfaction or strong motivation to restrict energy intake. Within the population of people who are

obese, there are some people who experience significant psychological and behavioral disturbances (32) or may live in poverty, and these people may be at risk for chronic obesity and may be less likely to lose weight in structured weight loss trials (58,79). This perspective suggests that there may be certain risk or protective factors for adverse psychological correlates of obesity. The following sections describe some of these factors.

## **B Gender**

Men tend to be less disturbed by obesity than women (32). This phenomenon is generally believed to stem from lower social pressure for thinness, and is reflected in higher self-esteem, quality of life, and marriage prospects among obese males (2,11,13).

## **C Ethnicity**

Minority adults (especially women) tend to be less concerned about overweight status and are less motivated to lose body weight than white adults (79–82). As noted earlier, African-American men and women have lower levels of body size dissatisfaction (56). Therefore, minorities may be at lower risk for developing mood or self-esteem problems associated with obesity, yet may also be less motivated to lose weight.

## **D Binge Eating**

Research has consistently found that obese binge eaters experience more psychological disturbances than obese people who do not frequently engage in binge eating (18,83,84). There has been considerable controversy about the distinction between a psychiatric syndrome called Binge Eating Disorder (BED) and binge eating as a behavioral correlate of obesity (85). Recent research studies that have used very strict definitions and have used structured interview methods for assessing BED have found that the syndrome as defined by the American Psychiatric Association (16) is actually quite rare (1–3%) even in obese people seeking treatment (86). However, binge eating as a symptom of obesity is much more common; significant binge eating is observed in 7–15% of obese adults (85). Men are slightly less likely to report binge eating than women, and most ethnic groups report comparable rates of binge eating. Binge eating and BED are associated with higher rates of depression (85). A recent study reported by Womble et al. (87) found that binge eating was highly correlated with obesity and that the combined influences of negative

affect and dietary restraint accounted for binge eating. This study and others (88) have suggested that binge eating is often determined by breaking dietary restraint or reduction of negative emotion. Thus, binge eating appears to be a significant risk factor for lower quality of life and may be viewed as a type of “coping behavior” for body dissatisfaction and negative affect that is commonly associated with obesity (87). Furthermore, binge eating is highly correlated with increased adiposity (89).

## **E Severity of Obesity**

In general, higher levels of obesity are negatively correlated with quality of life. For example, morbidly obese adults who seek obesity surgery report extremely negative reactions to their obesity. Furthermore, a national survey (90) found that obese women with a BMI  $\geq 36$  were more likely to report histories of rape, sexual molestation, or posttraumatic stress disorder than less overweight women. These data suggest that a history of trauma and/or binge eating may be associated with morbid obesity, significant mood disturbances, and a very low quality of life, but these cross-sectional studies do not inform us about the causes of lower quality of life that is correlated with obesity.

# **III QUALITY OF LIFE AND WEIGHT LOSS**

The process and outcome of weight loss would both be expected to affect quality of life. For most obese and overweight people, losing weight and maintaining the weight loss involves restriction of dietary intake, physiological readjustment, major lifestyle changes, and effort. For patients who undergo surgery, physiological functioning and food consumption are greatly altered beyond their control. Thus, the process of losing weight may have substantial impact on the life of the person engaged in the effort.

When successful, the result of this process would also likely impact one's life. Weight loss may produce improved health, increased work and activity capacity, altered appearance, and evidence of personal ability to change. Additionally, the altered dietary and exercise patterns necessary to maintain a weight loss represent long-term changes in the weight loser's life.

In this section we will review briefly the effects of losing weight on overall quality of life, mood, hunger, and body image. Most of the relevant data come from studies of people participating in weight loss interventions that are under study. Therefore, it is usually diffi-

cult to separate the effects of weight loss from the effects of the intervention and process required to achieve that loss. Further, in most cases the process is a structured intervention rather than a self-directed effort. Unless otherwise indicated, the findings reported should be assumed to refer to both the process of losing weight and the resultant weight loss.

### A Overall Quality of Life

Weight loss by obese persons is consistently associated with improved quality of life. Kolotkin and colleagues (2) compared scores on the Impact of Weight on Quality of Life scale at days 1 and 28 of a residential weight loss program. They found improvements in self-reported health, social functioning, work, activities of daily living, mobility, sexuality, and self-esteem. In a later study the same group (4) also found improvements in these areas among participants in a 2-week program. Further, the improvements tended to be greater for the 4-week program than for the 2-week program, and improvement in a total score was correlated significantly with amount of weight lost.

Fontaine et al. (91) compared scores on the SF-36 at the beginning and end of 13-week outpatient weight loss programs based on lifestyle modification and either aerobic exercise or lifestyle activity interventions. They found improvements on the physical functioning, role-physical, general health, vitality, and mental health domains, regardless of which physical activity program was encouraged. Other patients losing weight with the assistance of medication have demonstrated improvements in the Health, Mobility, and Activities of Daily Living scales of the Impact of Weight on Quality of Life scale (92). Hypertensive, dyslipidemic, or diabetic patients using prepared meals lost more weight and reported greater improvements on scales assessing physical and mental functioning than did patients in the standard diet condition (93).

Formerly severely obese patients who through gastric bypass surgery lost on average 43 kg showed improvements on all domains of the SF-36, physical and mental, and their postloss scores were equal to or better than population norms (94). The dramatic improvements appear more attributable to the large amount of weight lost than to the surgical procedure. Klem et al. (95) compared two groups of people who had lost on average ~ 66 kg—one group via surgery, and the other with various nonsurgical means; the subjects had maintained those losses for 2–3 years (95). Nearly all persons of both groups reported improvements in mood, self-confidence, quality of life, physical health, mobility,

energy level, and activity level. Similar majorities of both groups reported improvements in social interactions and job performance.

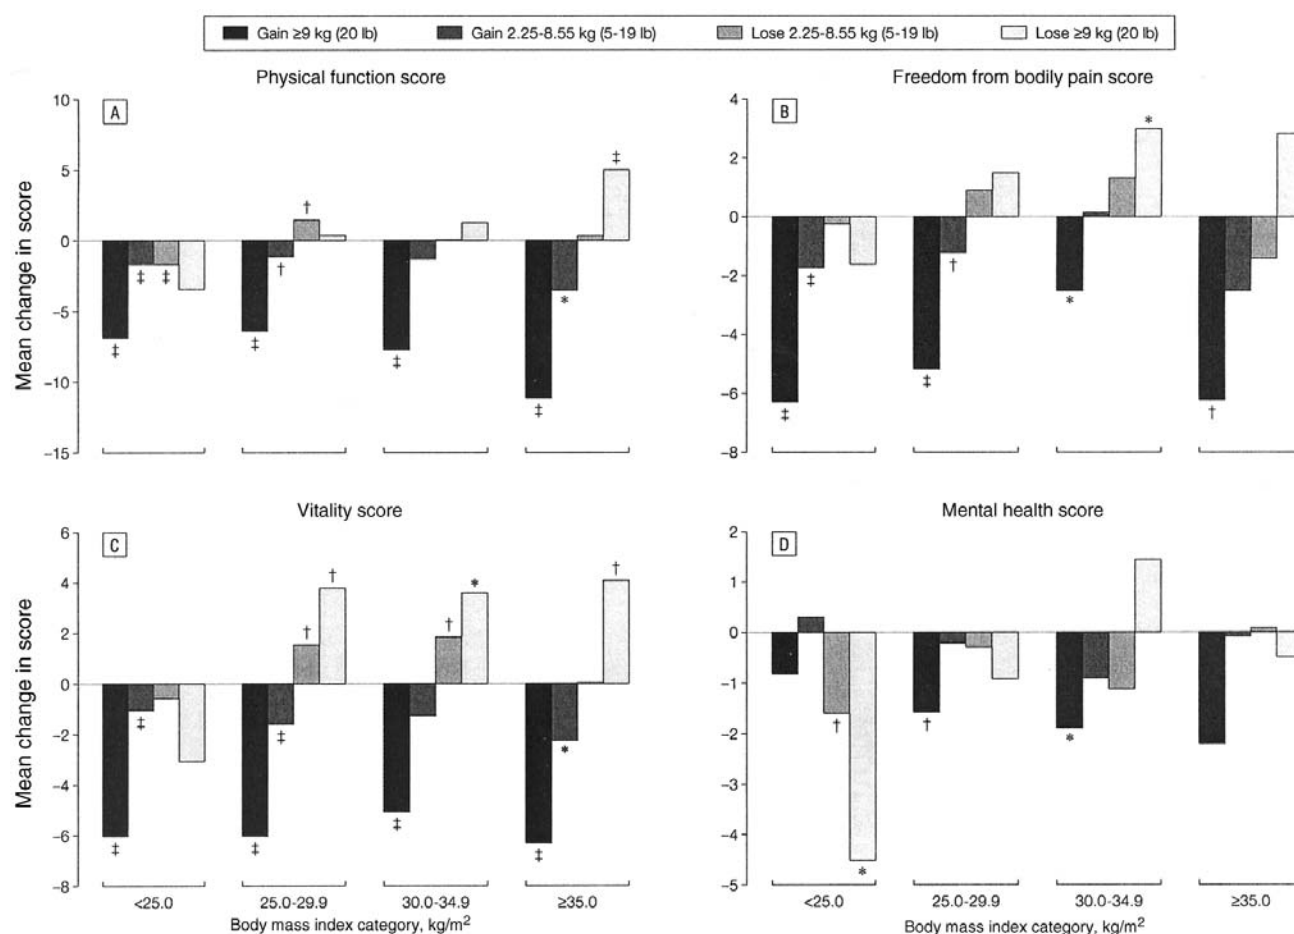

There is also evidence for a beneficial effect of weight loss achieved outside of professional programs and clinical trials. For example, Fine et al. (96) administered the SF-36 to a very large cohort of women, aged 46–71 years, at a baseline assessment and 4 years later, comparing changes in scores to changes in weight over the same time. As shown in Figure 3, overweight and obese women who lost weight over the period showed improvements in physical functioning, vitality, and bodily pain. Women who gained weight over the period showed decreased functioning in the same domains. This tended to be true for women over 65 as well as for those in the younger ages.

### B Mood

The notion that dieting has negative psychological consequences has had wide currency among the public and some professionals. The idea was first suggested by studies of substantial caloric restriction and weight loss by normal-weight subjects and by descriptions of patients' historical reports of symptoms during prior dieting (66,68,70,71). However, many subsequent, more relevant and highly controlled studies have shown at worst neutral and often beneficial mood changes among obese persons dieting to lose weight (18,97). Obese patients who have lost weight via moderate caloric restriction, very low calorie diets (VLCDs), or surgery frequently demonstrate improvements in depression and trait anxiety. With the dietary approaches, the improvements may be more commonly seen when a behavioral or lifestyle change program accompanies the diet (18, 98). However, anxiety and depression changes during VLCD are not related to diet variables such as whether the diet is food or formula based (99) or whether it is ketogenic (100).

Improvements in mood have also been observed among persons who have lost weight with a variety of means, most outside of professional programs. A group of 784 people who had lost on average 30 kg and maintained it for on average 5.5 years showed levels of distress and of depression lower than psychiatric-patient norms and similar to community norms (101).

The above-noted improvements in mood with weight loss occur in spite of certain physiological changes during dieting that in other circumstances suggest impairment in mood. For example, during VLCD, serum triiodothyronine (T3) is reduced substantially, but the degree of reduction is unrelated to changes in depres-

**Figure 3** Relationships between weight change and changes in SF-36 subscale scores over a 4-year period in women younger than 65 years. (From Ref. 96.) Asterisk indicates  $P < .01$ ; dagger,  $P < .05$ ; double dagger,  $P < .001$ ; and SF-36, Medical Outcomes Study Short-Form 36 Health Status Survey. A decrease in the bodily pain score indicates a decrease in functioning due to bodily pain.

sion (102). Nonoverweight volunteers undergoing a 3-week low-calorie diet (103) had indications of reduced availability of tryptophan for serotonin synthesis (lowered total plasma tryptophan, lowered ratio of tryptophan to competing amino acids). Whether this applies to overweight dieters remains to be seen.

Given the temporary nature of most weight losses, the possible impact of weight regain on mood deserves consideration. It has been asserted (68) that weight cycling may be associated with adverse psychological outcomes. However, there is little evidence in support of this position. Several cross-sectional comparisons of cyclers and noncyclers among clinical samples have failed to reveal consistent differences in psychological functioning (78). Foster et al. (104) used a prospective design to assess mood and eating-related variables among a

sample of obese women who had lost on average ~20 kg in dietary and behavioral treatment but after follow-up of more than 4 years were on average above their baseline weight. Despite the regain of more than the original loss, scores on measures of depression, binge eating, hunger, and disinhibition were still lower than at baseline. Changes in these measures were unrelated to amount of weight regain.

Among a community sample balanced on weight status, gender, and age, Foreyt et al. (105) examined the relations of recent and historical weight change patterns to measures of psychological status. Subjects were categorized by changes in measured weight over a 1-year period and by their subjective reports of whether they frequently lost and regained. There were no significant effects of 1-year measured weight change (in either

direction) on well-being or depression, but 1-year gainers and losers both reported having experienced more life change events than did 1-year maintainers. Subjects who denied historical patterns of losing and regaining reported greater well-being and control of eating compared to those who described their weight as typically fluctuating.

A related issue is whether weight gain *per se*, rather than weight gain following a weight loss, may have psychological effects. Analysis of psychological well-being scores for a subset of women in an NHANES I follow-up sample showed that those who had gained weight recently (at least 4.5 kg in the previous 6 months) had lower well-being scores than women who had maintained stable weights (106). This finding was seen in nonoverweight, overweight, and obese women. This study did not distinguish intentional from unintentional weight changes, or gain from regain; however, in this nationally representative sample there is no reason to believe that regain of previously intentionally lost weight accounted for more than a small minority of the cases of weight gain.

### C Hunger

It might be assumed that decreasing caloric intake below maintenance needs would inevitably lead to feelings of hunger. Several reports indicate that this is not always so. For example, with VLCDs, after the first week or 2, hunger and preoccupation with food either decrease or remain at prediet levels (99,100,107,108). Method of weight loss may affect level of hunger. Hunger and preoccupation with food have been found lower during a VLCD or following weight loss surgery than during moderate caloric restriction (19,99,107,108). However, one study comparing VLCD and moderate caloric restriction with type 2 diabetics found no differences in hunger ratings (109).

Another study (110) examined changes on the Perceived Hunger scale of the Eating Inventory (76) of obese women before and after 5–6 months in different treatment programs that included various diets. Across all treatment programs, hunger scores declined by ~18%. At baseline, higher hunger scores were seen among subjects who had higher scores on measures of depression and binge eating. Interestingly, weight loss was unrelated to baseline hunger scores or change in hunger scores (110).

Among the large group of successful weight loss maintainers noted earlier (101), Perceived Hunger scores were as low as those of normal-weight nondieters and lower than those of eating disorder samples. This

finding suggests that long-term maintenance of substantially lowered body weight is not accomplished at the cost of chronic hunger.

### D Body Image

As noted earlier, dissatisfaction with body size is a common problem associated with obesity, and body size dissatisfaction generally worsens with increased adiposity (56). The association of body size dissatisfaction and BMI has been observed in men and women, but it is less pronounced in African-Americans than in whites (56). Based on these findings, one would hypothesize that weight loss would be associated with improvement of body image. In general, this hypothesis has been supported for persons who lose weight through lifestyle behavior modification and obesity surgery (2,14,19,38,111). However, many other factors are also associated with improved body image that accompanies weight loss. An important variable is the person's weight loss goals. Foster et al. (112) found that most participants in weight loss trials do not achieve weight losses that meet even minimally acceptable weight goals. These findings suggest that improvement of body image may not be a direct product of weight loss, but instead may be caused by a complex interaction of changes in body weight, ideal body size goals, and personality characteristics related to the importance of thinness and physical appearance for self-esteem.

## IV ASSESSMENT OF QUALITY OF LIFE

### A Introduction

Quality of life has been measured using a wide variety of assessment procedures, ranging from very general measures of quality of life to very specific behavioral and psychological indicators of quality of life. This section provides a summary of some of the most common methods that have been used in research pertaining to obesity and quality of life.

### B Overall Quality of Life

The two questionnaires most widely used to measure overall quality of life in obesity research are the Impact of Weight on Quality of Life questionnaire and the Medical Outcomes Study Short-Form Health Survey (SF-36) (3,113). The Impact of Weight on Quality of Life 74-item questionnaire asks the respondent to indicate the degree to which obesity negatively affects his

or her functioning in eight areas: Health, Social/Interpersonal, Work, Mobility, Self-Esteem, Sexual Life, Activities of Daily Living, and Comfort with Food (2,4). Recently, a shorter (31-item) version has been developed (114).

The 36-item Medical Outcomes Study Short Form (SF-36) (113) is a very widely used self-report index of health status and medical outcomes as related to a variety of medical conditions and treatments. It produces scores on eight scales measuring physical and emotional functioning and general health perceptions.

As previously described, both the Impact of Weight on Quality of Life Scale and the SF-36 have shown the ability to detect differences associated with differences in body weight. Further, these measures have been found to be sensitive to changes in body weight and can be used as indices for benefits of weight loss upon health and well-being.

There are a number of brief surveys and questionnaires that have been developed as measures of quality of life (115). Most of these questionnaires assess very general happiness with life (116) and/or family relationships (117). These measures have not received widespread use, in comparison to the SF-36 and Impact of Weight on Quality of Life.

### C Mood and Personality

Another common approach for measuring quality of life is to assess global indicators of mood or personality. The Beck Depression Inventory (BDI) (118–120) has been used frequently for this purpose. The BDI has 21 items that measure the symptoms of depression. It has been used in many studies of many different physical and mental health problems over the past 30 years (121), including obesity (122). Studies of mood disturbances associated with obesity (25,123) and clinical trials have found the BDI to be a sensitive and useful tool.

The State-Trait Anxiety Inventory (STAI) (124) is a commonly used measure of situational (state) and generalized (trait) anxiety. The STAI requires rating 40 anxiety symptoms; it has been studied for > 30 years and has been found to be a reliable and valid measure of anxiety in a wide variety of physical and mental health disorders, including obesity (54).

The Symptom Checklist-90 (125) measures nine symptom domains ranging from depression and anxiety to obsessive-compulsive disorder and psychotic problems. The SCL-90 also has three global measures of symptom severity that may be more useful as measures of quality of life than the nine scales that measure specific symptom domains. The SCL-90 has been validated

in a variety of studies over the past 30 years and has been used extensively in research related to obesity (122).

One of the most frequently used measures of personality is the Minnesota Multiphasic Personality Inventory (126). The MMPI-2 has three validity scales that test for “faking good” and “faking bad.” The MMPI-2 also has 10 clinical scales (126) and hundreds of supplemental scales (127,128). In general, obese people do not have high scores on any of the MMPI-2 clinical scales. Furthermore, the MMPI-2 is not sensitive to change during clinical trials. Therefore, the primary purpose of the MMPI-2 is to screen for psychological problems at baseline. However, since it is quite long (567 questions), there are several other less time-consuming methods that can be used for the same purpose.

The PRIME-MD (129) is one alternative to the MMPI-2 for screening of common psychiatric disorders. This method was developed as a cost-efficient procedure to be used by primary care physicians to screen for the presence of depression, anxiety disorders, eating disorders, psychosis, and substance abuse. The original version of the PRIME-MD included a survey of common mental health symptoms that was completed by the patient. The physician then interviewed the patient about specific problem behaviors to establish a psychiatric diagnosis. A more recent version of the PRIME-MD (130) relies exclusively upon the patient’s self-report via questionnaire. This method is equally valid as the original PRIME-MD for screening common mental health problems. A much longer interview for psychiatric problems is the Structured Clinical Interview for DSM-IV axis I Disorders (SCID) (131). This semistructured interview format has been found to be a reliable and valid method for establishing psychiatric diagnoses based on the diagnostic criteria established by the American Psychiatric Association (16). The SCID is primarily used in research studies where it is important to screen for a wide variety of mental health problems.

### D Eating Behavior/Disturbed Eating

Over the past 20 years, many assessment methods have been developed to measure the symptoms of anorexia nervosa, bulimia nervosa, and binge-eating disorders. Other methods have been established to measure specific behavioral, cognitive, or affective symptoms associated with disturbed patterns of eating.

Two semistructured interviews have been tested as measures of eating disorder symptoms. The Eating Disorder Examination (132–134) was developed to assess the core features of bulimia nervosa. In recent years, the

EDE has been used to define eating disorders, including binge eating disorder. The EDE has undergone 12 revisions and is generally considered to be one of the best methods for assessing core symptoms of eating disorders. The Interview for Diagnosis of Eating Disorders, fourth version (IDED-IV) (135) was developed specifically for the purpose of establishing a diagnosis of anorexia nervosa, bulimia nervosa, binge-eating disorder, or eating disorder not otherwise specified, using the diagnostic criteria established by the American Psychiatric Association (16). The reliability and validity of the IDED-IV has been established in a number of studies, and it has been used to reliably differentiate binge-eating disorder from simple obesity (135). Therefore, the most important use for the IDED-IV in obesity research may be its potential for reliably screening for the presence of eating disorders, including binge-eating disorder.

Several questionnaires have been developed for measuring a wide range of eating behaviors and eating disorder symptoms. The Eating Behavior Inventory (EBI) (136) was developed to assess behaviors prescribed by behavioral weight loss programs, e.g., self-monitoring of food intake and body weight, refusing offers of food, eating at only one place, shopping from a list, and eating in response to emotions. Factor analysis found three scales: control over eating, use of behavioral weight control methods, and use of stimulus control procedures (137). The EBI has been found to be a reliable and valid measure, and it is sensitive to treatment effects. Unfortunately, it has not found widespread use in obesity research.

The most widely used "broad-band" measure of disturbed eating is the Eating Disorder Inventory-2 (EDI-2) (138). The EDI-2 was developed for use with eating disorders, and only two of the EDI-2 scales are applicable to obesity: the bulimia scale, and the body dissatisfaction scale. Thus, despite the established reliability and validity of the EDI, it has only limited potential for use with obesity. Two recently developed questionnaires may be more useful in obesity. One is the Weight Loss Behavior Scale (139). This self-report inventory was developed specifically for use in treatment outcome research related to obesity. The reliability and validity of the WLBS has been supported in a recent study (139), and it measures five symptom domains: (1) concern with dieting and weight; (2) exercise; (3) overeating; (4) avoidance of fattening foods; and (5) emotional eating. Another questionnaire, the Multidimensional Assessment of Eating Disorder Symptoms (140), was developed for assessment of treatment outcome with eating disorders; it has six scales: (1) binge

eating; (2) restrictive eating; (3) purgative behavior; (4) fear of fatness; (5) avoidance of forbidden foods; and (6) depression.

## **E Dietary Restraint and Overeating/Binge Eating**

A variety of questionnaires have been developed for measuring intention to restrict caloric intake to manage body weight. As noted earlier, dietary restraint has been hypothesized to result in "disinhibited eating." The first measure of dietary restraint was developed by Herman and Mack (141) and was later revised to a 10-item scale (142). Researchers began to question whether dietary restraint and overeating were necessarily linked. These questions led to the development of two new measures that measured the two constructs, dietary restraint and overeating, as separate variables. Stunkard and Messick (76) developed the Three Factor Eating Questionnaire, and it is now called the Eating Inventory (143). The Eating Inventory has three scales—dietary (cognitive) restraint, disinhibition, and perceived hunger. Later research found that the dietary restraint and disinhibition scales were not correlated, which supports the conclusion that intention to diet and overeating may not be causally linked (74). A series of studies (73,74,77) have reported that flexible approaches to dieting are not associated with overeating, but that rigid approaches to dieting are associated with overeating. This line of research led to the development of a revision of the Dietary Restraint scale that has two dimensions: rigid and flexible dieting (144). At about the time the Three Factor Eating Questionnaire was developed, Van Strien et al. (145) reported a similar self-report inventory called the Dutch Eating Behavior Questionnaire; it measures restrained eating, emotional eating, and external eating. The reliability and validity of these scales have been established in a series of studies (146).

Several questionnaires have been developed as measures of binge eating. The Binge Eating Questionnaire is a nine-item self-report inventory that measures binge eating (147). The Binge Eating Scale is a 16-item questionnaire that has been used more frequently in research studies of binge eating (148). The Questionnaire of Eating and Weight Patterns was developed to screen for the presence of binge-eating disorder (149). Recent studies have found that all of these questionnaires overestimate the prevalence of binge eating and binge-eating disorder (85,86). The Eating Disorder Examination, described earlier, is a semistructured interview method that includes questions for measuring binge eating that provides a more accurate measure of consuming

objectively large amounts of food (134). Also as mentioned, the IDED-IV (135) structured interview has been validated as an objective method for defining binge-eating disorder (86).

## F Body Image

Until recently, questionnaires have been most frequently used in studies of body image, body dissatisfaction, and obesity. Two of the more frequently used questionnaires are the body dissatisfaction scale of the EDI-2 (138) and the Body Shape Questionnaire (150). Recently, two nonquestionnaire measures of body image associated with obesity have been developed. Williamson et al. (56) validated the Body Image Assessment for Obesity (BIA-O). The BIA-O measures estimates of current, ideal, and reasonable body size, using pictures of body silhouettes that vary in terms of body size and shape (from very thin to very obese). The discrepancy between current and ideal body size estimates was validated as a measure of body size dissatisfaction. The BIA-O has been validated for use with Caucasian men and women and African-American men and women. Stewart et al. (65) validated a computerized body image assessment procedure called the Body Morph Assessment (BMA). The BMA also measures estimates of current, ideal, and reasonable body size and these estimates were validated against the BIA-O. Thus far, the BMA has only been studied with Caucasian women, which limits its use with a diverse population.

## V CONCLUSIONS

Research has found that obesity is associated with lower overall quality of life. Obese people experience considerable distress stemming from excess body weight, but only a minority of obese adults develop clinical psychiatric syndromes. In addition to social influences, the impact of obesity on quality of life is also a function of personal characteristics, e.g., severity of obesity, gender, ethnic background, and the presence of behavioral characteristics such as binge eating. Weight loss generally results in improved overall quality of life, mood, hunger, and body image. Conversely, weight gain is associated with worsened quality of life. In recent years, many assessment instruments that measure quality of life have been developed and validated. In conclusion, research on quality of life and obesity has been very active over the past ten years, leading to a much better understanding of how obesity and weight loss (and gain) are related to personal well-being. It is recommended

that measures of quality of life routinely be included in obesity treatment outcome studies as additional important indicants of treatment effectiveness.
